1. BACKGROUND

1.1 Introduction
This overview represents the updated European Association of Urology (EAU) guidelines for Non-muscle-invasive Bladder Cancer (CIS, Ta, T1). The information presented is limited to urothelial carcinoma, if not specified otherwise. Aim is to provide practical guidance on the clinical management of non-muscle-invasive bladder cancer with a focus on clinical presentation and recommendations.

The EAU Guidelines Panel on Non-muscle-invasive Bladder Cancer consists of an international multidisciplinary group of clinicians, including a pathologist and a statistician.

It must be emphasised that clinical guidelines present the best evidence available but following the recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients - also taking personal values and preferences and individual circumstances of patients into account.

Separate EAU guidelines documents are available addressing upper urinary tract tumours (1), muscle-invasive bladder cancer (2), and primary urethral carcinomas (3).

1.2 Methodology

1.2.1 Data Identification
The systematic literature search for each section of the Non-muscle-invasive Bladder Cancer Guidelines was performed by the panel members. For identification of original and review articles, Medline, Web of Science, and Embase databases were used. For the current update, all articles published between 2010 and 2012 on non-muscle-invasive bladder cancer were considered. Focus of the searches was identification of all level 1 scientific papers (randomised controlled trials (RCTs), systematic reviews (SRs), and meta-analyses of RCTs) in accordance with the EAU guidelines methodology.

1.2.2 Level of evidence and grade of recommendation
References in the text have been assessed according to their level of scientific evidence (LE), and guideline recommendations have been graded follow the listings in Tables 1 and 2, based on the Oxford Centre for Evidence-based Medicine Levels of Evidence (4). Grading aims to provide transparency between the underlying evidence and the recommendation given.

*Modified from Sackett et al. (4).

It should be noted that when recommendations are graded, the link between the LE and grade of recommendation (GR) is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level of evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. There may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful. Whenever this occurs, it is indicated in the text as “upgraded based on panel consensus”. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences, and costs when a grade is assigned (5-7).

The EAU Guidelines Office does not perform structured cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever these data are available, the expert panel will include the information.

1.3 Publication history
The first European Association of Urology (EAU) Guidelines on Bladder Cancer were published in 2000 (8). In 2004 it was decided to develop separate guidelines for muscle-invasive and infiltrative bladder cancer and a separate scientific publication on upper urinary tract tumours was presented (9), which was updated and has been included in the EAU Guidelines compilation print since 2011 (10). The complete updates of guidelines for non-muscle-invasive bladder cancer were prepared in 2006, 2008 and 2011 (11-14). Since 2011 the EAU Guidelines on TaT1 tumours and CIS were integrated in one guidelines document (14).

Several scientific summaries have been published in the EAU scientific journal, European Urology (9,15-19). A quick reference document (pocket guidelines) is available presenting the main findings of the Non-muscle-invasive Bladder Cancer Guidelines. This document follows the updating cycle of the underlying large texts.

All material can be viewed and downloaded for personal use at the EAU website. The EAU website also includes a selection of translations and republications produced by national urological associations: http://www.uroweb.org/guidelines/online-guidelines/.

This document was peer-reviewed prior to publication.

1.3.1 Summary of changes
For all chapters the literature has been assessed.

Chapter 4 - Classification: a clear definition of non-muscle-invasive bladder cancer is presented. Since appropriate classification and grading directly influences treatment decisions, additional information on pathological parameters has been added.

Chapter 5 - Diagnosis: an illustration on bladder diagram to facilitate the description of cystoscopy finding has been added. The new data on endoscopic diagnosis and pathological evaluation of the tissue included in this section resulted in a number of changes in the recommendations.

Chapter 6 - Predicting disease recurrence and progression: the new stratification of patients into 3 risk groups facilitating treatment recommendation is presented.

Chapter 7 - Adjuvant treatment: updated information on intravesical chemo- and immunotherapy is provided. The definition and stratification of BCG toxicity and side-effects is provided in an overview table. The definition of BCG failures has been specified.

Chapter 8: Radical cystectomy for NMIBC: the indication criteria were updated.

1.4 Potential conflict of interest statement
The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guidelines/.

1.5 References

2. EPIDEMIOLOGY

Bladder Cancer (BC) is the most common malignancy of the urinary tract and the seventh most common cancer in men and the 17th in women. The worldwide age standardised incidence rate is 9 per 100,000 for men and 2 per 100,000 for women (2008 data) (1). In the European Union (EU) age standardised incidence rate is 27 per 100,000 for men and six per 100,000 for women (1).

Incidence varies between regions and countries; in Europe, the highest age standardised incidence rate has been reported in Spain (41.5 in men and 4.8 in women) and the lowest in Finland (18.1 in men and 4.3 in women) (1). The variations can partly be attributed to different methodology and quality of data collection, thus warranting care in the interpretation of results (2,3).

The world global age standardised mortality rate is 3 for men versus 1 per 100,000 for women. In the EU, age standardised mortality rate is 8 for men and 3 per 100,000 for women, respectively (1). In 2008 BC was the eighth most common cause of cancer-specific mortality in Europe (1).

The incidence of BC has decreased in some registries possibly reflecting decreased impact of causative agents, mainly smoking and occupational exposure (4). The mortality of BC has also decreased, possibly reflecting increased standard of care (5).

Approximately 75% of patients with BC present with a disease that is confined to the mucosa (stage Ta, CIS) or submucosa (stage T1). These categories are grouped as non-muscle-invasive bladder tumours. Non-muscle invasive BC (NMIBC) has a high prevalence due to low progression rates and long-term survival in many cases; patients with muscle-invasive BC (MIBC) are at higher risk of cancer-specific mortality (3). The prevalence of BC is among the highest of all urological malignancies (1).

3. RISK FACTORS

Increasing evidence suggests that genetic predisposition has a significant influence on bladder cancer incidence, especially via its impact on susceptibility to other risk factors (3,6). Tobacco smoking is the most important risk factor for BC, accounting for ~50% of cases (3,7) (LE: 3). Tobacco smoke contains aromatic amines and polycyclic aromatic hydrocarbons, which are renally excreted.

Occupational exposure to aromatic amines, polycyclic aromatic hydrocarbons and chlorinated hydrocarbons is the second most important risk factor for BC, accounting in the modern era for ~10% of all cases. Such occupational exposure occurs mainly in industrial branches processing paint, dye, metal and petroleum products (3,8-10) (LE: 3).

Although the significance of the amount of fluid intake is uncertain, chlorination of drinking water and subsequent levels of trihalomethanes is potentially carcinogenic, and exposure to arsenic in drinking water increases BC risk (3,11) (LE: 3). The relation between personal hair dye use and BC risk remains uncertain; increased risk has been suggested in users of permanent hair dyes with NAT2 slow acetylation phenotype) (12,13).

The exposure to ionizing radiation is connected with increased risk of BC (LE: 3). It is suggested that cyclophosphamide and pioglitazone are weakly associated with BC risk (3). Schistosomiasis, a chronic endemic cystitis based on recurrent infection with a parasitic trematode, is a cause of bladder cancer, particularly squamous cell carcinoma (3) (LE: 3).

4. CLASSIFICATION

4.1 Definition of non-muscle-invasive bladder cancer
A papillary tumour confined to the mucosa is classified as stage Ta according to the Tumour, Node, Metastasis (TNM) classification system. Tumours that have invaded the lamina propria are classified as stage T1. Ta and T1 tumours can be removed by transurethral resection (TUR), and therefore they are grouped under the heading of NMIBC for therapeutic purposes. Also included under this heading are flat, high-grade tumours that are confined to the mucosa, and classified as CIS (Tis). However, molecular biology techniques and clinical experience have demonstrated the highly malignant potential of CIS and T1 lesions. Therefore, the terms NMIBC and superficial BC are suboptimal descriptions. The latter term should no longer be used. Whenever the terminology NMIBC is used in individual cases, the tumour stage and grade should be mentioned.
4.2  Tumour, Node, Metastasis Classification (TNM)
The 2002 TNM classification approved by the Union International Contre le Cancer (UICC) has been widely accepted. This version was updated in 2009, but it has no changes for bladder tumours (Table 3) (14).

4.3  Histological grading of non-muscle-invasive bladder urothelial carcinomas
In 1998, a new classification of non-invasive urothelial tumours was proposed by the World Health Organization (WHO) and the International Society of Urological Pathology (ISUP) (1998 WHO/ISUP classification) and published by the WHO in 2004 (15,16) (Table 4). Its major contribution is a detailed histological description of the various grades, which uses specific cytological and architectural criteria. A website (www.pathology.jhu.edu/bladder) that illustrates examples of the various grades has been developed to further improve accuracy in using the system.

</tr>
</tbody>
</table>

The 2004 WHO classification of the flat lesions includes urothelial hyperplasia, reactive urothelial atypia, atypia of unknown significance, dysplasia, and CIS. Among non-invasive papillary urothelial lesions, the 2004 WHO grading differentiates between papillary urothelial neoplasm of low malignant potential (PUNLMP) and low-grade and high-grade urothelial carcinomas.

Papillary urothelial neoplasms of low malignant potential (PUNLMPs) are defined as lesions that do not have cytological features of malignancy but show normal urothelial cells in a papillary configuration. Although they have a negligible risk for progression, they are not completely benign and still have a tendency to recur.

The intermediate grade (Grade 2), which was the subject of controversy in the 1973 WHO classification, has been eliminated (17–19) (Figure 1). The published comparisons, however, have not clearly confirmed that the WHO 2004 classification has better reproducibility than the 1973 classification (20,21).

The prognostic value of both grading systems (WHO 1973 and 2004) has been confirmed. Attempts to demonstrate better prognostic value of one of the systems, however, have yielded controversial results (17–20,22–24). The majority of clinical trials published to date on TaT1 bladder tumours have been performed using the 1973 WHO classification, and therefore, the following guidelines are based on this version. Until the prognostic role of WHO 2004 is validated by more prospective trials, both classifications should be used.

Figure 1: Stratification of tumours according to grade in the WHO 1973 and 2004 classifications (19)*

</tbody>
</table>

1973 WHO Grade 1 carcinomas have been reassigned to PUNLMP and Low-grade carcinomas in 2004 WHO classification, and Grade 2 carcinomas to Low-grade and High-grade carcinomas. All 1973 WHO Grade 3 carcinomas have been reassigned to High-grade carcinomas. Reproduced with permission from Elsevier.

4.4 Inter- and intraobserver variability in staging and grading

Despite well-defined criteria for the diagnosis of urothelial carcinoma, there is significant variability among pathologists for diagnosis of CIS, for which agreement is achieved in only 70–78% of cases (25,26) (LE: 2a). There is interobserver variability in classification of stage T1 versus Ta tumours and tumour grading in both 1997 and 2004 classifications. The general conformity in staging and grading is between 50 and 60% (20,25–29) (LE: 2a).
4.5 **Further promising pathological parameters**

Some novel parameters based on pathological investigation of resected tissue have been evaluated and considered for subclassification and prognostic purposes.

In patients with T1 tumours, the depth and extent of invasion into the lamina propria (T1 substaging) can be evaluated. The prognostic value of this evaluation has been demonstrated by some retrospective cohort studies (30-33) (LE: 3). The presence of lymphovascular invasion has been reported as an unfavourable prognostic factor in T1 tumours (34) (LE: 3). It must be presented in pathological reports.

Detection of the micropapillary variant of urothelial carcinoma represents a poor prognostic factor even if it is non-muscle invasive at the time of diagnosis (35,36) (LE: 3). In micropapillary urothelial tumours with T1 invasion, some cases with distant metastases have been confirmed (35). Moreover, the risk of understaging in these tumours is substantial (37).

Rare cases of non-invasive squamous cell carcinoma in the bladder with poor prognosis have been described (38). Novel molecular markers, particularly FGFR3 mutation status, are promising but need further evaluation (17,33,39-41).

4.6 **Specific character of CIS and its clinical classification**

CIS is a flat, high-grade, non-invasive urothelial carcinoma. Macroscopically, CIS can be missed at cystoscopy or be considered as an inflammatory lesion if it is not biopsied. It is often multifocal and can occur not only in the bladder but also in the upper urinary tract, prostatic ducts, and prostatic urethra (42).

CIS is classified into one of four different clinical types (43):

- **Primary**: isolated CIS with no previous or concurrent papillary tumours and no previous CIS;
- **Secondary**: CIS detected during follow-up of patients with a previous tumour that was not CIS;
- **Concurrent**: CIS in the presence of any other urothelial tumour in the bladder;
- **Recurrent**: Repeat occurrence of isolated CIS after initial successful response to intravesical treatment.

5. **DIAGNOSIS**

5.1 **Patient history**

Patient history should be taken and recorded for all important information with possible connection to BC, including risk factors and history of suspect symptoms.

5.2 **Symptoms**

Haematuria is the most common finding in NMIBC. Ta, T1 tumours do not cause bladder pain and rarely present with lower urinary tract symptoms (LUTS). In patients who do complain of these symptoms, particularly in those with irritative LUTS refractory to symptomatic treatment, CIS might be suspected.

5.3 **Physical examination**

Physical examination does not reveal NMIBC.

5.4 **Imaging**

5.4.1 **Intravenous urography and computed tomography**

Intravenous urography (IVU) is used to detect filling defects in the calyces, renal pelvis and ureters, and hydronephrosis, which can indicate the presence of a ureteral tumour. Large exophytic tumours may be seen as filling defects in the bladder. The necessity to perform routine IVU once a bladder tumour has been detected is questioned because of the low incidence of significant findings obtained with this method (44-46) (LE: 2a). The incidence of upper urinary tract tumours is low (1.8%), but increases to 7.5% in tumours located in the trigone (45) (LE: 2b). The risk of tumour recurrence in the upper urinary tract during follow-up increases in multiple and high-risk tumours (47) (LE: 2b).

In most centres, computed tomography (CT) urography is used as an alternative to conventional IVU (48). Especially in muscle-invasive tumours of the bladder and upper urinary tract tumours, CT urography gives more information than IVU does (including status of lymph nodes and neighbouring organs). However, CT urography has the disadvantage of higher radiation exposure compared to IVU.
5.4.2 Ultrasonography
Ultrasonography (US) is often used as the initial tool to assess the urinary tract. This is not only because it avoids the use of contrast agents, but also because sensitive transducers have improved imaging of the upper urinary tract and bladder.

Transabdominal US permits characterisation of renal masses, detection of hydroureterism, and visualisation of intraluminal masses in the bladder. It can be as accurate as IVU for diagnosis of upper urinary tract obstruction (44) (LE: 3). US is therefore a useful tool for detection of obstruction in patients with haematuria, however, it cannot exclude the presence of upper tract tumours.

CIS cannot be diagnosed with imaging methods (IVU, CT urography or US).

5.5 Urinary cytology
Examination of voided urine or bladder-washing specimens for exfoliated cancer cells has high sensitivity in high-grade tumours but low sensitivity in low-grade tumours. As a result of loss of cell cohesion in the epithelial lining of the bladder in CIS, there is a larger number of floating cells in the urine, as well as a high degree of anaplasia. The sensitivity of cytology for CIS detection is 28-100% (49) (LE: 2b). Cytology is thus useful when a high-grade malignancy or CIS is present. However, urinary cytology often is negative in the presence of low-grade cancer. Positive voided urinary cytology can indicate a urothelial tumour anywhere in the urinary tract, from the calyx to the ureters, bladder, and proximal urethra. Negative cytology, however, does not exclude the presence of a tumour in the urinary tract.

Cytological interpretation is user-dependent (50). Evaluation can be hampered by low cellular yield, urinary tract infections, stones, or intravesical instillations. In experienced hands however, the specificity exceeds 90% (51) (LE: 2b). Cytology should be performed on fresh urine with adequate fixation. Morning urine is not suitable because of the frequent presence of cytolysis.

5.6 Urinary molecular marker tests
There are specified general requirements for good bladder cancer markers (51):

- The test must be as technically simple as possible (preferably a point-of-care test, with readily available results, easy to perform, with a short learning curve);
- Low cost;
- Good reliability and reproducibility;
- For individual patient populations and clinical situations, the test should have a high specificity to avoid unnecessary workup because of false-positive results, and high sensitivity to avoid the risk of missing a tumour;
- For clinical settings, it is of utmost importance to detect high-risk urothelial cancer before it escapes curative treatment.

Driven by the low sensitivity of urine cytology, extensive laboratory research has developed numerous urinary tests for BC detection (51-57). Considering the frequency of cystoscopy for follow-up, markers for recurrent urothelial cancer would be especially useful.

Numerous reviews of urinary markers have appeared in recent years (51-53,55-65). None of these markers have been accepted as standard diagnostic or follow-up procedures in routine urology or in guidelines. Some urine tests that have been evaluated in several laboratories/centres and in studies with sufficient numbers of patients are listed in Table 5. Sensitivity and specificity should be used to compare studies on urine tests because they remain constant, whereas positive and negative predictive values vary between populations with different numbers of positive and negative events (54,57).

The following conclusions can be drawn about the existing tests. Sensitivity is usually higher at the cost of lower specificity than urine cytology (51-57) (LE: 3). Benign conditions and BCG influence many urinary marker tests (51-65) (LE: 3). Sensitivity and specificity of a urinary marker test depend on the clinical context of the patient (screening, primary detection, follow-up (high risk), and follow-up (low/intermediate risk)) (54-57) (LE: 3). For example, sensitivity of a given urinary marker is higher for detection of a primary lesion than a recurrent lesion (54) (LE: 3). Patient selection explains the wide range in performance of the markers listed in Table 5.

Unlike other urine tests, some false-positive results of UroVysion and microsatellite analysis can be attributed to occult disease and thus identify those patients who are more likely to experience subsequent recurrence. It might also be useful to predict response to intravesical therapy (66-68) (LE: 3). Microsatellite analysis is the most promising of the methods listed in Table 5 (69-71).

5.7 Practical application of urinary cytology and markers

The following objectives of urinary cytology or molecular tests must be considered:

- Screening of the population at risk of BC. The application of haematuria dipstick, NMP22 or UroVysion in BC screening in high-risk populations has been reported (72,73). The low incidence of BC in the general population and the short lead time impair feasibility and cost-effectiveness (57,72-74). Routine application of screening is not recommended.

- Exploration of patients after haematuria or other symptoms suggestive of BC (primary detection). It is generally accepted that none of the tests can replace cystoscopy. However, urinary cytology or markers can be used as an adjunct to cystoscopy to detect invisible tumours, particularly CIS. In this setting, sensitivity for high-grade tumours and specificity are particularly important. Urinary cytology is highly specific but urinary markers lack this high specificity and are not recommended for primary detection. Future studies should explore the feasibility of urine markers preceding/replacing cystoscopy in patients with microscopic haematuria.

- Facilitate surveillance of NMIBC (54,59,75,76).
  
  a. Follow-up of high-risk NMIBC: High-risk tumours should be detected early in follow-up, and the percentage of tumours missed should be as low as possible. Therefore, the best surveillance strategy for these patients will continue to include frequent cystoscopy and cytology. Specificity is more important than sensitivity in this subset of patients, because the urinary markers are used as an adjunct to cystoscopy. A urinary marker other than cytology is not recommended for high-risk NMIBC surveillance.

  b. Follow-up low/intermediate risk NMIBC: To reduce the number of cystoscopy procedures, urinary markers should be able to detect recurrence before the tumours are large and numerous. The limitation of urinary cytology is its low sensitivity for low grade/risk recurrences. Several urinary markers are better but still do not detect half of the low-grade tumours that are detected by cystoscopy (54,57) (LE: 3).

According to current knowledge, no urinary marker can replace cystoscopy during follow-up or help to lower cystoscopic frequency in routine fashion. One prospective randomised study confirmed that knowledge of positive test results (microsatellite analysis) can improve the quality of follow-up cystoscopy (77) (LE: 1b). It supports the adjunctive role of a non-invasive urine test performed before follow-up cystoscopy. (77).

5.8 Cystoscopy

The diagnosis of papillary BC ultimately depends on cystoscopic examination of the bladder and histological evaluation of the resected tissue. CIS is diagnosed by a combination of cystoscopy, urine cytology, and histological evaluation of multiple bladder biopsies (78).

Cystoscopy is initially performed in the office. A flexible instrument with topical intraurethral anaesthetic lubricant instillation results in better compliance, especially in men (79). Careful inspection of the whole urothelial lining in the bladder should be performed to prevent missing the tumour.

If a bladder tumour has been visualised in earlier imaging studies, diagnostic cystoscopy can be omitted because the patient will undergo TUR (80).
A careful description of the findings is necessary. It should include the site, size, number, and appearance (papillary or solid) of the tumours, as well as a description of mucosal abnormalities. Use of a bladder diagram is recommended (Figure 2).

Figure 2: Bladder diagram

5.9 Transurethral resection of Ta, T1 bladder tumours

The goal of the TURB in Ta, T1 BC is to make the correct diagnosis and remove all visible lesions. It is a crucial procedure in the diagnosis and treatment of BC.

TUR of the bladder (TURB) should be performed systematically as follows:

- Procedure is initiated with careful bimanual palpation under general or spinal anaesthesia;
- Insertion of the resectoscope, in men under visual guidance, with inspection of the whole urethra;
- Inspection of the whole urothelial lining of the bladder;
- Biopsy from prostatic urethra (if indicated, see lower);
- Cold-cup bladder biopsies (if indicated, see lower);
- Resection of the tumour.

The strategy of resection depends on the size of the lesion. Small tumours (<1 cm) can be resected en bloc, which includes the entire tumour and part of the underlying bladder wall. Larger tumours should be resected separately in fractions, including the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle, and the edges of the resection area. This approach provides good information about the vertical and horizontal extent of the tumour and helps to improve resection completeness (81) (LE: 3). Deep resection is not necessary in small, apparently low-grade lesions with a previous history of low-grade Ta (G1) tumour.

- In patients with palpable lesions before TURB, bimanual palpation should be repeated after resection
- The protocol is formulated, which must describe all previous steps of the procedure, as well as extent and completeness of resection
- An order form for pathological evaluation is prepared.

The specimens from different biopsies and resection fractions must be referred to the pathologist in separate containers and labelled separately, to enable him/her to make a correct diagnosis. Cauterisation should be avoided as much as possible during TURB to prevent tissue destruction.

Complete and correct TURB is essential to achieve a good prognosis (82). It has been confirmed that absence of detrusor muscle in the specimen is associated with a significantly higher risk of residual disease.
and early recurrence (83) (LE: 2b).

Training in the methods of TURB should be included in teaching programmes. It has been shown that surgical experience can improve TURB results (84).

5.10 Office-based fulguration
In patients with a history of small, low-grade (WHO 2004 classification)/G1 (1973 classification) Ta tumours, fulguration of small papillary recurrences on an outpatient basis can reduce the therapeutic burden and can be a treatment option (85) (LE: 3).

5.11 Bladder- and prostatic urethral biopsies
CIS can present as a velvet-like, reddish area that is indistinguishable from inflammation, or it might not be visible at all.

When abnormal areas of urothelium are seen, it is advised to take cold-cup biopsies or biopsies with a resection loop. Biopsies from normal-looking mucosa, so-called random (mapping) biopsies, should be performed in patients with positive urinary cytology and absence of visible bladder tumour, in addition to upper tract work-up/diagnostics. It is recommended to take biopsies from the trigone, bladder dome, and from the right, left, anterior and posterior bladder walls.

In patients with TaT1 tumours, mapping/random biopsies are not routinely recommended. The likelihood of detecting CIS, especially in low-risk tumours, is extremely low (< 2%) (86) (LE: 2a). Material obtained by random or directed biopsies must be sent for pathological assessment in separate containers as specified previously.

Involvement of the prostatic urethra and ducts in men with NMIBC has been reported. Palou et al. (87) showed that in 128 men with T1G3 BC, the incidence of CIS in prostatic urethra was 11.7% (LE:2b). The risk of prostatic urethra or duct involvement seems to be higher if the tumour is located on the trigone or bladder neck, in the presence of bladder CIS and multiple tumours (88,89) (LE: 3). When bladder CIS is suspected, or cytology is positive with no evidence of bladder tumour, or abnormalities of prostatic urethra are visible, prostatic urethral biopsies are recommended (87). The biopsy is taken from abnormal areas and from the precollicular area (between 5 and 7 o'clock positions) using a resection loop. In primary NMIBC when stromal invasion is not suspected, a cold-cup biopsy with forceps can be performed (90).

5.12 New TURB techniques
5.12.1 New resection techniques
Compared to monopolar resection, the bipolar electrocautery system may reduce the risk of complications (e.g., bladder perforation due to obturator nerve stimulation) (91) (LE: 3). This benefit however must be confirmed by a prospective trial.

5.12.2 New methods of tumour visualisation
As a standard procedure, cystoscopy and TUR are performed using white light. However, the use of white light can lead to missing lesions that are present but not visible, which is why new technologies are being developed.

5.12.2.1 Photodynamic diagnosis (fluorescence cystoscopy)
Photodynamic diagnosis (PDD) is performed using violet light after intravesical instillation of 5-aminolaevulinic acid (ALA) or hexaminolaevulinic acid (HAL). It has been confirmed that fluorescence-guided biopsy and resection are more sensitive than conventional procedures for detection of malignant tumours, particularly for CIS (92,93) (LE: 2a). In the systematic review and meta-analysis, PDD had higher sensitivity than white light endoscopy in the pooled estimates for both patient (92% versus 71%) and biopsy (93% versus 65%) level analyses (93).

PDD had lower specificity than white light endoscopy (63% versus 81%) (93). False-positivity can be induced by inflammation or recent TUR, and during the first 3 months after BCG instillation (94,95) (LE: 3).

Prospective randomised studies evaluating the impact of ALA fluorescence-guided TURB on disease recurrence rate have shown controversial results (93,96,97).

A large, multicentre, prospective randomised trial that compared HAL fluorescence-guided TURB with standard TURB reported an absolute reduction of no more than 9% in the recurrence rate within 9 months in the HAL arm. Median time to recurrence improved from 9.4 months in the white light arm to 16.4 months in the HAL arm after mean follow-up of 53 and 55 months, respectively (98,99) (LE: 1b).

The value of fluorescence cystoscopy for improvement of the outcome in relation to progression rate or survival remains to be demonstrated.

In summary, PDD improves tumour detection rate, particularly in CIS. HAL but not ALA fluorescence-guided TURB was shown to have a beneficial effect on disease recurrence rate.
Photodynamic diagnosis is recommended in patients who are suspected of harbouring a high-grade tumour, for example, for biopsy guidance in patients with positive cytology or with a history of high-grade tumour. The additional costs of the equipment and instillation for PDD should be taken into account.

5.12.2.2 Narrow band imaging
In narrow band imaging (NBI) the contrast between normal urothelium and hypervascular cancer tissue is enhanced by filtering white light into two bandwidths of 415 and 540 nm, which are absorbed by haemoglobin. Initial studies have demonstrated improved cancer detection by NBI-guided biopsies and resection (100) (LE: 3). These findings should be confirmed in large multi-institutional studies.

5.13 Second resection
The significant risk of residual tumour after initial TURB of Ta, T1 lesions has been demonstrated (82,101) (LE: 2a). Persistent disease after resection of T1 tumours has been observed in 33-53% of patients (101-106). Moreover, the tumour is often understaged by initial resection. The likelihood that a T1 tumour has been understaged and muscle-invasive disease detected by second resection ranges from 4 to 25%. This risk has increased up to 50% in some radical cystectomy series, although these studies have only enrolled selected patients (102,107-109) (LE: 2a). Treatment of a TaT1 high-grade tumour and a T2 tumour is completely different; therefore, correct staging is important. It has been demonstrated that a second TURB can increase the recurrence-free survival (104,105) (LE: 2a).

A second TURB is recommended in the following situations:
• After incomplete initial TUR;
• If there was no muscle in the specimen after initial resection, with exception of Ta G1 tumours and primary CIS;
• In all T1 tumours;
• In all G3 tumours, except primary CIS.

There is no consensus about the strategy and timing of second TURB. Most authors recommend resection at 2-6 weeks after initial TURB. The procedure should include resection of the primary tumour site.

5.14 Pathological report
Pathological investigation of the specimen obtained by TURB and biopsies is an essential step in the diagnosis and treatment decision making of bladder cancer. High quality of resected and submitted tissue is essential for correct pathological assessment. The presence of sufficient muscle is necessary for correct assignment of pT category. Individual biopsies and portions of the tumour should be submitted in separate containers, and labelled individually. Pathologists should obtain from urologists order forms with sufficient clinical information regarding each sample, including the location of each sample.

The pathological report should specify (110):
• location of the evaluated sample (information obtained from the urologist order form);
• grade of each lesion;
• depth of tumour invasion (stage);
• presence of CIS;
• presence of detrusor muscle in the specimen;
• presence of lymphovascular invasion (LVI);
• presence of aberrant histology.

Close cooperation between urologists and pathologists is recommended.
## 5.15 Guidelines for primary assessment of non-muscle-invasive bladder cancers

6. PREDICTING DISEASE RECURRENTCE AND PROGRESSION

6.1 Ta, T1 tumours

The classic way to categorise patients with Ta, T1 tumours with or without concomitant CIS is to divide them into risk groups based on prognostic factors derived from multivariate analyses. Using such a technique, it has been proposed to divide patients into low-, intermediate- and high-risk groups (111). When using these risk groups, however, no distinction is usually drawn between the risk of disease recurrence and disease progression. Although prognostic factors may indicate a high risk of recurrence, the risk of progression might still be low, while other tumours might have a high risk of both recurrence and progression.

In order to predict separately the short-term and long-term risks of disease recurrence and progression in individual patients, the European Organization for Research and Treatment of Cancer (EORTC) Genito-Urinary Cancer Group (GUCG) has developed a scoring system and risk tables (112). The basis for these tables is the EORTC database, which provides individual patient data for 2,596 patients diagnosed with TaT1 tumours, who were randomised in seven EORTC-GUCG trials. Patients with CIS alone were not included. Seventy-eight percent of patients received intravesical treatment, mostly chemotherapy. However, they did not undergo a second TUR or receive maintenance BCG. The scoring system is based on the six most significant clinical and pathological factors:

- number of tumours;
- tumour size;
- prior recurrence rate;
- T category;
- presence of concurrent CIS;
- tumour grade.

Table 6 illustrates the weights applied to various factors for calculating the total scores for recurrence and progression. Table 7 shows the total scores stratified, as in the original article (112), into four categories that reflect various probabilities of recurrence and progression at 1 and 5 years.

Note: Electronic calculators for Tables 6 and 7, which have been updated for the iPhone, iPad and Android phones and tablets, are available at http://www.eortc.be/tools/bladdercalculator/.

A scoring model for BCG-treated patients that predicts the short- and long-term risks of recurrence and progression has been published by the Club Urológico Español de Tratamiento Oncológico (CUETO) (Spanish Urological Oncology Group). It is based on an analysis of 1,062 patients from four CUETO trials that compared different intravesical BCG treatments. Patients received 12 instillations during 5-6 months. No immediate postoperative instillation or second TUR was performed in these patients. The scoring system is based on evaluation of seven prognostic factors:

- sex;
- age;
- prior recurrence status;
- number of tumours;
- T category;
- associated CIS;
- tumour grade.

Using these tables, the calculated risk of recurrence is lower than that obtained by the EORTC tables. For progression, probability is lower only in high-risk patients (113). The lower risks in the CUETO tables may be attributed to using BCG, which is a more effective instillation therapy. Validations of the EORTC scoring system using the CUETO patients treated with BCG and in an independent patient population with long-term follow-up has confirmed its prognostic value (114,115) (LE: 2a).

A scoring model for BCG-treated patients that predicts the short- and long-term risks of recurrence and progression has been published by the Club Urológico Español de Tratamiento Oncológico (CUETO) (Spanish Urological Oncology Group). It is based on an analysis of 1,062 patients from four CUETO trials that compared different intravesical BCG treatments. Patients received 12 instillations during 5-6 months. No immediate postoperative instillation or second TUR was performed in these patients. The scoring system is based on evaluation of seven prognostic factors:

- sex;
- age;
- prior recurrence status;
- number of tumours;
- T category;
- associated CIS;
- tumour grade.

Using these tables, the calculated risk of recurrence is lower than that obtained by the EORTC tables. For progression, probability is lower only in high-risk patients (113). The lower risks in the CUETO tables may be attributed to using BCG, which is a more effective instillation therapy. Validations of the EORTC scoring system using the CUETO patients treated with BCG and in an independent patient population with long-term follow-up has confirmed its prognostic value (114,115) (LE: 2a).

Further prognostic factors have been described in selected patient populations. Female sex and CIS in the prostatic urethra are important prognostic factors in T1G3 patients treated with an induction course of BCG (87) (LE: 2b). Recurrence at 3 months was the most important predictor of progression in T1G2 tumours treated with TURB (116) (LE: 2b). The prognostic value of pathological factors, particularly T1 substaging, has been discussed elsewhere (see Chapter 4.4).

More work is required to determine the role of molecular markers in improving the predictive accuracy of the currently existing risk tables (114,117).

### 6.2 Carcinoma in situ

Without any treatment, approximately 54% of patients with CIS progress to muscle-invasive disease (118) (LE: 3). Unfortunately, there are no reliable prognostic factors that can be used to predict the course of the disease and specify the most dangerous cases. Publications are based on retrospective analyses of small series of patients, and their conclusions are not homogeneous. Some studies have reported a worse prognosis in concurrent CIS and T1 tumours compared to primary CIS (119,120), in extended CIS (121) and in CIS in the prostatic urethra (87) (LE: 3).

Various publications have shown that the response to intravesical treatment with BCG or chemotherapy is an important prognostic factor for subsequent progression and death caused by bladder cancer (113-116). Approximately 10-20% of complete responders eventually progress to muscle-invasive disease, compared with 66% of non-responders (122-124) (LE: 2a).
6.3 **Recommendation for patients’ stratification in risk groups**

Based on available prognostic factors and particularly data from the EORTC risk tables, the Guidelines Panel recommends stratification of patients into three risk groups that will facilitate treatment recommendations. Their definition, which takes into account the EORTC risk tables probabilities of recurrence and especially progression, can be found in Table 8. The recommendation is similar but not identical to that provided by the International Bladder Cancer Group (125).

For individual prediction of the risk of tumour recurrence and progression at different intervals after TURB, application of EORTC risk tables and calculator is strongly recommended.

**Table 8: Risk group stratification**

6.3.1 **Recommendations for stratification of NMIBC**

| Stratify patients into three risk groups according to Table 8. | B |
| Application of EORTC risk tables and calculator for individual prediction of the risk of tumour recurrence and progression in different intervals after TURB. | B |

7. **ADJUVANT TREATMENT**

7.1 **Intravesical chemotherapy**

Although state-of-the-art TUR by itself can eradicate a Ta, T1 tumour completely, these tumours commonly recur and can progress to MIBC. The high variability in the 3-month recurrence rate indicates that TUR is incomplete or provokes recurrences in a high percentage of patients (82). It is therefore necessary to consider adjuvant therapy in all patients.

7.1.1 **One, immediate, postoperative intravesical instillation of chemotherapy**

Early single instillation has been shown to function by the destruction of circulating tumour cells resulting from TUR, and by an ablative effect (chemoablation) on residual tumour cells at the resection site and on small overlooked tumours (126-129) (LE: 3).

In a meta-analysis of 1,476 patients, one immediate instillation of chemotherapy after TUR significantly reduced recurrence rate by 11.7% compared to TUR alone (130) (LE: 1a). The majority of patients (> 80%) in the meta-analysis had a single tumour. A similar efficacy was reported in two more recent studies (131,132), with subgroup analyses suggesting that immediate instillation is most effective in tumour types with the lowest tendency towards recurrence, that is, in single primary or small tumours. Mitomycin C, epirubicin, and doxorubicin have all shown a beneficial effect, with no efficacy comparisons made between the drugs (130) (LE: 1a).

There is evidence from one subgroup analysis and one combined analysis that immediate instillation might have an impact on recurrence even when further adjuvant instillations are given (133,134) (LE: 2a).

Prevention of tumour cell implantation should be initiated within the first hours after cell seeding. Within a few hours, the cells are implanted firmly and are covered by extracellular matrix (127,136-138) (LE: 3).
3). In all single instillation studies, the instillation was administered within 24 h. To maximise the efficacy of immediate instillation, one should devise flexible practices that allow the instillation to be given as early as possible, that is, in the recovery room or even in the operating theatre.

Immediate instillation of postoperative chemotherapy should be omitted in any case of overt or suspected intra- or extraperitoneal perforation, which is most likely to appear in extensive TUR procedures, and in situations with bleeding that requires bladder irrigation. Clear instructions should be given to the nursing staff to control the free flow of the bladder catheter at the end of the instillation. Severe complications have been reported in patients with drug extravasation (139).

7.1.2 Additional adjuvant intravesical chemotherapy instillations
The need for further adjuvant intravesical therapy depends on prognosis. In low-risk patients (Tables 7 and 8), a single immediate instillation reduces the risk of recurrence and is considered as the standard treatment (130) (LE: 1a). No further treatment should be given in these patients before subsequent recurrence. For other patients, however, a single immediate instillation remains an incomplete treatment because of the considerable likelihood of recurrence and/or progression (Tables 7 and 8).

A large meta-analysis of 3,703 patients from 11 randomised trials showed a highly significant 44% reduction in the odds of recurrence at 1 year in favour of chemotherapy over TUR alone (140). This corresponds to an absolute difference of 13–14% in the number of patients with recurrence. Contrary to chemotherapy, two meta-analyses have demonstrated that BCG therapy may reduce the risk tumour progression (141,142) (LE: 1a) (see section 7.2.1). Moreover, BCG maintenance therapy appears to be significantly better in preventing recurrences than regimens with mitomycin C (MMC) or epirubicin (143-145) (see section 7.2.1) (LE: 1a). However, BCG causes significantly more side effects than chemotherapy does (145) (LE: 1a).

It is still controversial for how long and how frequently chemotherapy instillations should be given. From a systematic review of the literature of RCTs, which compared different schedules of intravesical chemotherapy instillations, one can only conclude that the ideal duration and intensity of the schedule remains undefined because of conflicting data (146). The available evidence does not support any treatment longer than 1 year (LE: 3).

7.1.3 Options for improving efficacy of intravesical chemotherapy
Some promising data have been presented about enhancing the efficacy of MMC using microwave-induced hyperthermia (Synergo) or electromotive drug administration (EMDA) in patients with high-risk tumours. The current evidence, however, is limited. The number of patients in the prospective series applying the microwave-induced hyperthermia was small and data on progression were inconclusive. In one study of 212 patients comparing BCG with sequential BCG and electromotive MMC, a significant benefit was found in favour of the electromotive arm regarding recurrence and progression (147,148) (LE: 2b). Still, both treatment modalities are considered to be experimental.

One RCT using MMC has demonstrated that adapting urinary pH, decreasing urinary excretion, and buffering the intravesical solution reduces the recurrence rate (149) (LE: 1b). Another trial reported that a 1-h instillation of MMC is better than 30 min, but no efficacy comparisons are available for 1- and 2-h instillations (150) (LE: 3).

Another RCT using epirubicin has documented that concentration is more important than treatment duration (151) (LE: 1b). In view of these data, which need confirmation, it seems advisable to ask the patient not to drink on the morning before instillation, and to dissolve the drug in a buffered solution at optimal pH.

7.2 Intravesical Bacillus Calmette-Guérin (BCG) immunotherapy
7.2.1 Efficacy of BCG
Five meta-analyses have confirmed that BCG after TUR is superior to TUR alone or TUR and chemotherapy for prevention of recurrence of non-muscle-invasive tumours (143,152-155) (LE: 1a). Three recent RCTs of intermediate- and high-risk tumours have been conducted. BCG was compared with combination of epirubicin and interferon (156), MMC (157) or epirubicin alone (144). All of these studies have confirmed the superiority of BCG for prevention of tumour recurrence (LE: 1a). It has been shown that the effect was long lasting (144,157) and was also observed in a separate analysis of patients with intermediate-risk tumours (144).

One meta-analysis (143) has evaluated the individual data from 2,820 patients enrolled in nine RCTs that have compared MMC versus BCG. In the trials with BCG maintenance, a 32% reduction in the risk of recurrence for BCG compared to MMC was found (P < 0.0001), whereas there was a 28% increase in the risk of recurrence (P = 0.006) for patients treated with BCG in the trials without BCG maintenance.

Two meta-analyses have demonstrated that BCG therapy prevents, or at least delays, the risk of tumour progression (141,142) (LE: 1a). A meta-analysis carried out by the EORTC-GUCG has evaluated data from 4,863 patients (81.6% with papillary tumours and 18.4% with primary or concurrent CIS) enrolled in 24
RCTs. Five different BCG strains were used, and in 20 of the trials, some form of BCG maintenance was used. Based on a median follow-up of 2.5 years, in 260 out of 2,658 patients (9.8%) treated with BCG, tumours progressed compared to 304 out of 2,205 (13.8%) in the control groups (TUR alone, TUR plus intravesical chemotherapy, or TUR plus other immunotherapy). This shows a reduction of 27% in the odds of progression with BCG maintenance treatment ($P = 0.0001$). The size of the reduction was similar in patients with TaT1 papillary tumours and in those with CIS (142). A recent RCT with long-term observation has demonstrated significantly fewer distant metastases and better overall- and disease-specific survival in patients treated with BCG compared to epirubicin (144) (LE: 1b). On the contrary, a meta-analysis of individual patient data was not able to confirm any statistically significant difference between MMC and BCG for progression, survival and cause of death (143).

The conflicting results in the outcomes of the studies can be explained by different patient characteristics, duration of follow-up, methodology and statistical power. The majority of studies were however able to show a reduction in the risk of progression in high- and intermediate-risk tumours if BCG was applied including a maintenance schedule.

Two other meta-analyses have suggested a possible bias in favour of BCG by the inclusion of patients who were previously treated with intravesical chemotherapy (158,159). In the most recent meta-analysis, however, BCG maintenance was more effective than MMC also in patients who were previously treated with chemotherapy (143) (LE: 1a).

### 7.2.2 Optimal BCG schedule

Induction BCG instillations are classically given according to the empirical 6-weekly schedule that was introduced by Morales in 1976 (160). For optimal efficacy, BCG must be given in a maintenance schedule (141-143,155) (LE: 1a). In the EORTC-GU group meta-analysis, only patients who received maintenance BCG benefited. Many different maintenance schedules have been used, ranging from a total of 10 instillations given in 18 weeks, to 27 over 3 years (161). The meta-analysis was unable to determine which BCG maintenance schedule was the most effective (142). In their meta-analysis, Böhle et al. concluded that at least 1 year of maintenance BCG is required to obtain superiority of BCG over MMC for prevention of recurrence or progression (141,155) (LE: 1a).

The optimal number of induction instillations and optimal frequency and duration of maintenance instillations remain unknown (162). However, in an RCT of 1,355 patients, the EORTC has recently shown that when BCG is given at full dose, 3 years maintenance reduces the recurrence rate as compared to 1 year in high-risk but not in intermediate-risk patients. There were no differences in progression or overall survival (159) (LE: 1b). The benefit of the two additional years of maintenance in the high-risk patients should be weighed against its added costs and inconveniences.

### 7.2.3 BCG toxicity

BCG intravesical treatment is associated with more side effects compared to intravesical chemotherapy (145) (LE: 1a). Serious side effects however are encountered in < 5% of patients and can be treated effectively in almost all cases (163) (LE: 1b). It has been shown that maintenance schedule is not associated with increased risk of side effects comparing to induction course (163).

Major complications can appear after systemic absorption of the drug. Thus, contraindications of BCG intravesical instillation should be respected.

BCG should not be administered (absolute contraindications):
- during the first 2 weeks after TUR;
- in patients with macroscopic haematuria;
- after traumatic catheterisation;
- in patients with symptomatic urinary tract infection.

The presence of leukocyturia or asymptomatic bacteriuria is not a contraindication for BCG application, and antibiotic prophylaxis is not necessary in these cases (164,165) (LE: 3).

BCG should be used with caution (relative contraindication) in immunocompromised patients (immunosuppression, human immunodeficiency virus (HIV) infection) (166), although some small studies have shown similar efficacy and no increase in complications comparing to non-immuno-compromised patients (167,168) (LE: 3).

The management of side effects after BCG should reflect their type and grade. Recommendations for individual situations have been provided by the International Bladder Cancer Group (IBCG) and by a Spanish group (169,170) (Table 9).

7.2.4 **Optimal dose of BCG**

To reduce BCG toxicity, instillation of a reduced dose was proposed. Comparing one-third dose to full-dose BCG in 500 patients, CUETO found no overall difference in efficacy. However, it has been suggested that a full dose of BCG is more effective in multifocal tumours (LE: 1b). Although fewer patients have reported toxicity with the reduced dose, the incidence of severe systemic toxicity was similar in the standard- and reduced-dose groups. The same Spanish group has shown in a prospective RCT that one-third of the standard dose of BCG might be the minimum effective dose for intermediate-risk tumours. A further reduction to one-sixth dose resulted in a decrease in efficacy for prevention of recurrence with no decrease in toxicity (LE: 1b).

The EORTC did not find any difference in toxicity between one-third and full dose BCG, however, the former was associated with a higher recurrence rate, especially when it was given only for 1 year (LE: 1b).

7.2.5 **BCG strain**

There is no conclusive evidence that there may be a difference in clinical efficacy between various BCG strains.

7.2.6 **Indications for BCG**

Although BCG is a very effective treatment, there is a consensus that not all patients with NMIBC should be treated with BCG due to the risk of toxicity. Ultimately, the choice of treatment depends upon the patient’s risk (Table 8):

- BCG does not alter the natural course of low-risk tumours (Table 8), and could be considered as overtreatment for this patient category.
- In patients with high-risk tumours, for whom radical cystectomy is not carried out, 1-3 years full-dose maintenance BCG is indicated. The additional beneficial effect of the second and third years of maintenance on recurrence in high-risk patients should be weighed against its added costs and inconveniences.
- In intermediate-risk patients, full-dose BCG with 1 year maintenance is more effective than chemotherapy for prevention of recurrence; however, it has more side effects than chemotherapy. For this reason both BCG with maintenance and intravesical chemotherapy remain an option. The final choice should reflect the individual patient’s risk of recurrence and progression as well as efficacy and side effects of each treatment modality.

7.3 **Specific aspects of treatment of CIS**

7.3.1 **Treatment strategy**

If concurrent CIS is found in association with MIBC, therapy is determined according to the invasive tumour. The detection of CIS with TaT1 tumours increases the risk of recurrence and progression of TaT1 tumours (112,113) and further treatment is mandatory. The treatment strategy is generally based on the criteria that are summarised in Chapters 7.1, 7.2, 7.4 and 8.

CIS cannot be cured by an endoscopic procedure alone. Histological diagnosis of CIS must be followed by further treatment, either intravesical BCG instillations or radical cystectomy (LE: 4). No consensus exists about whether conservative therapy (intravesical BCG instillations) or aggressive therapy (radical cystectomy) should be done. There has been a lack of randomised trials of instillation therapy and early radical cystectomy as immediate primary treatment. Tumour-specific survival rates after early radical cystectomy for CIS are excellent, but as many as 40-50% of patients might be overtreated (177) (LE: 3).

7.3.2 **Cohort studies**

In retrospective evaluations of patients with CIS, a complete response rate of 48% was achieved with intravesical chemotherapy and 72-93% with BCG (118-121,178) (LE: 2a). Up to 50% of complete responders might eventually show recurrence with a risk of invasion and/or extravesical recurrence (121,161,178,179) (LE: 3).

7.3.3 **Prospective randomised trials**

Unfortunately, there have been few randomised trials in patients with CIS alone. Thus, the power to detect differences in treatment results has been low and the reliability of the conclusions is limited (177).

A meta-analysis of clinical trials that has compared intravesical BCG to intravesical chemotherapy (MMC, epirubicin, or adriamycin) in patients with CIS has shown a significantly increased response rate after BCG and a reduction of 59% in the odds of treatment failure with BCG (OR = 0.41, P = 0.0001). In trials that have compared BCG with MMC, the long-term benefit of BCG was smaller, but BCG was superior to MMC in trials with BCG maintenance (OR = 0.57, P = 0.04) (180) (LE: 1a).

In an EORTC-GUCG meta-analysis of tumour progression, in a subgroup of 403 patients with CIS, BCG reduced the risk of progression by 35% as compared to intravesical chemotherapy or different
immunotherapy (OR = 0.65, 95% CI = 0.36-1.16, P = 0.10) (LE: 1b). There has been no single trial that has demonstrated superiority of combined BCG and MMC over BCG alone (181).

In summary, compared to chemotherapy, BCG treatment of CIS increases the complete response rate, the overall percentage of patients who remain disease free, and reduces the risk of tumour progression (LE: 1a).

7.3.4 Treatment of extravesical CIS
Patients with CIS are at high risk of extravesical involvement: in the upper urinary tract and in the prostatic urethra. Solsona et al. have found that 87 of 138 patients (63%) with CIS developed extravesical involvement initially or during follow-up (182). Patients with extravesical involvement had worse survival than those with bladder CIS alone (182) (LE: 3).

In the prostate, CIS might be present only in the epithelial lining of the prostatic urethra or in the prostatic ducts (177). These situations should be distinguished from tumour invasion into the prostatic stroma, which is staged as T4a, and for which immediate radical cystoprostatectomy is mandatory.

Patients with CIS in the epithelial lining of the prostatic urethra can be treated by intravesical instillation of BCG. TUR of the prostate can improve contact of BCG with the prostatic urethra (78,177,183) (LE: 3).

In patients with prostatic duct involvement, there are promising results, but only from short series, so the data are insufficient to provide clear treatment recommendations (184). No conclusive results have been obtained with conservative therapy, therefore, radical surgery should be considered (183) (LE: 3).

Treatment of CIS that involves the upper urinary tract is discussed in the Guidelines on Urothelial Carcinomas of the Upper Urinary Tract.

7.4 Treatment of failure of intravesical therapy

7.4.1 Failure of intravesical chemotherapy
Patients with non-muscle-invasive recurrence of BC after chemotherapy regimen can profit from BCG instillations. Prior intravesical chemotherapy has no impact on the effect of BCG instillation (143) (LE: 1a).

7.4.2 Recurrence and failure after intravesical BCG immunotherapy

BCG-refractory tumour:

1. If high-grade, non-muscle-invasive papillary tumour is present at 3 months (185). Further conservative treatment with BCG is connected with increased risk of progression (122,186) (LE: 3).

2. If CIS (without concomitant papillary tumour) is present at both 3 and 6 months. In patients with CIS present at 3 months, an additional BCG course can achieve a complete response in > 50% of cases (42) LE: 3).

3. If high-grade tumour appears during BCG therapy.*

* Patients with low-grade recurrence during or after BCG treatment are not considered as BCG failure.

7.4.3 Treatment of BCG failure and recurrences after BCG

Treatment recommendations are provided in Table 11. They reflect categories mentioned in the previous paragraph and tumour characteristics at the time of recurrence.

Patients with BCG failure are unlikely to respond to further BCG therapy; therefore, radical cystectomy is the preferred option. The results of various studies suggest that repeat BCG therapy is appropriate for non-high-grade and even for some high-grade recurrent tumours (188,189) LE: 3).

Additionally, there are several bladder preservation strategies available that can be categorised as immunotherapy, chemotherapy, device-assisted therapy, and combination therapy (190). Changing from BCG to these options can yield responses in selected cases with BCG treatment failure for NMIBC (188, 191-199) (LE: 3). However, experience is limited and treatments other than radical cystectomy must be considered oncologically inferior at the present time (122,185,186) (LE: 3).
7.5 Recommendations for adjuvant therapy in Ta, T1 tumours and for therapy of CIS

The type of intravesical therapy should be based on the risk groups shown in Tables 8 and 11. A

One immediate chemotherapy instillation is recommended in tumours presumed to be at low or intermediate risk. A

In patients with low-risk Ta tumours, one immediate instillation of chemotherapy is recommended as the complete adjuvant treatment. A

In patients with intermediate-risk Ta T1 tumours, one immediate instillation of chemotherapy should be followed by 1 year full-dose BCG treatment, or by further instillation of chemotherapy for a maximum of 1 year. A

In patients with high-risk tumours, full-dose intravesical BCG for 1-3 years is indicated. A

In patients with CIS in the epithelial lining of the prostatic urethra, TUR of the prostate followed by intravesical instillation of BCG is an option. C

In patients at highest risk of tumour progression (Table 11), immediate radical cystectomy should be considered. C

In BCG refractory tumours, radical cystectomy is indicated. B

Intravesical chemotherapy.

One immediate instillation of chemotherapy should be omitted in any case of overt or suspected intraperitoneal perforation (after extensive TURB, or bleeding requiring bladder irrigation). C

The optimal schedule of further intravesical chemotherapy instillation and its duration is not defined and should not exceed 1 year. C

If intravesical chemotherapy is given, it is advised to use the drug at its optimal pH and to maintain the concentration of the drug during instillation by reducing fluid intake. B

The length of individual instillation should be 1-2 hours. C

BCG intravesical immunotherapy.

Absolute contraindications of BCG intravesical instillation are: during the first 2 weeks after TUR; in patients with macroscopic haematuria; after traumatic catheterization; and in patients with symptomatic urinary tract infection. C

The management of side effects after BCG intravesical instillation should reflect their type and grade (Table 9). C

8. RADICAL CYSTECTOMY FOR NON-MUSCLE-INVASIVE BLADDER CANCER

If cystectomy is indicated before pathologically confirmed progression into muscle-invasive tumour, immediate (immediately after NMIBC diagnosis) and early (after BCG failure) radical cystectomy can be distinguished. There are several reasons to consider radical cystectomy for selected patients with NMIBC:

- The staging accuracy for T1 tumours by TURB is low with 27-51% of patients being upstaged to muscle-invasive tumour at radical cystectomy (90,108,200-211) (LE: 3).
- Some patients with non-muscle invasive tumours experience disease progression in muscle-invasive disease (Table 7).
- It has been shown retrospectively that patients with high-risk NMIBC who undergo early rather than delayed cystectomy for tumour relapse after initial treatment with TURB and BCG have a better survival rate (212) (LE: 3).

Potential benefit of radical cystectomy must be weighed against the risk, morbidity, and impact on quality of life of radical cystectomy. It is reasonable to propose immediate radical cystectomy to those patients with non-muscle-invasive tumour who are at highest risk of progression. These are (35,87,112,113) (LE: 3):

- multiple and/ or large (> 3 cm) T1, high-grade (G3) tumours;
- T1, high-grade (G3) tumours with concurrent CIS;
- recurrent T1, high-grade (G3) tumours;
- T1G3 and CIS in prostatic urethra;
- micropapillary variant of urothelial carcinoma.
It is recommended to discuss immediate radical cystectomy and conservative treatment with BCG instillation. Patients should be informed about the benefits and risks of both approaches. Individual factors like gender and age of the patient should be considered because of worse prognosis between females and life-long risk of progression after BCG in high risk tumours.

Radical cystectomy is strongly recommended in patients with BCG refractory tumours, as mentioned above. Delay of radical cystectomy might lead to decreased disease-specific survival (213) (LE: 3). In patients in whom radical cystectomy is performed at the time of pathological non-muscle-invasive disease, the 5-year disease-free survival rate exceeds 80% (214-219) (LE: 3).

9. FOLLOW-UP OF PATIENTS WITH NON-MUSCLE-INVASIVE BLADDER TUMOURS

As a result of the risk of recurrence and progression, patients with TaT1 bladder tumours and with CIS need to be followed up; however, the frequency and duration of cystoscopy and imaging should reflect the individual patient’s degree of risk. Using risk tables (see Tables 6 and 7), we are able to predict the short- and long-term risks of recurrence and progression in individual patients, and can adapt the follow-up schedule accordingly (112). When planning the follow-up schedule and methods the following aspects should be considered:

- The prompt detection of muscle-invasive and high-grade non-muscle-invasive recurrence is crucial because a delay in diagnosis and therapy can be life-threatening.
- Tumour recurrence in the low-risk group is nearly always low stage and low grade. Small, non-invasive (Ta), low-grade papillary recurrence does not present an immediate danger to the patient, and early detection is not essential for successful therapy (220-227) (LE: 2b). Fulguration of small papillary recurrences on an outpatient basis could be a safe option that reduces the therapeutic burden (85) (LE: 3). Some authors have even defended temporary surveillance in selected cases (226-228) (LE: 3).
- The first cystoscopy after TUR at 3 months is a very important prognostic indicator for recurrence and progression (112,116,122,229-231) (LE: 1a). The first cystoscopy should thus always be performed 3 months after TUR in all patients with TaT1 BC.
- In tumours at low risk, the risk of recurrence after 5 recurrence-free years is low (230) (LE: 3). Discontinuation of cystoscopy or its replacement with less-invasive methods can be considered (231).
- In tumours originally at intermediate or high risk, recurrences after 10 years tumour-free interval are not unusual (232) (LE: 3). Therefore, lifelong follow-up is recommended (231).
- The risk of upper urinary tract recurrence increases in patients with multiple and high-risk tumours (47) (LE: 3).
- Positive urine test results have a positive impact on the quality of performed follow-up cystoscopy (77) (LE: 1b). It supports the adjunctive role of urine tests during follow-up.

No non-invasive method has been proposed that can replace endoscopy, therefore, follow-up is based on regular cystoscopy (Section 5.8). There has been a lack of randomised studies that have investigated the possibility of safely reducing the frequency of follow-up cystoscopy. The following recommendations are therefore based mostly on retrospective experience.

1. INTRODUCTION

The last European Association of Urology (EAU) guidelines on upper urinary tract tumours known as upper tract urothelial carcinomas (UTUCs) were published in 2011 (1). The EAU Guidelines Working Panel for UTUCs has prepared the current guidelines to provide evidence-based information for the clinical management of these rare tumours and to help clinicians incorporate these recommendations into their practice. The current update is based on a structured literature search.

2. METHODOLOGY

2.1 Data identification
A Medline search was performed on urothelial malignancies and UTUC management using combinations of the following terms: urinary tract cancer; urothelial carcinomas; upper urinary tract; urothelial carcinoma; renal pelvis; ureter; chemotherapy; nephroureterectomy; adjuvant treatment; neoadjuvant treatment; recurrence; risk factors; nomogram; and survival. The publications concerning UTUCs were mostly retrospective, including some large multicentre studies. Due to the scarcity of randomised data, articles were selected for these guidelines based on the following criteria: evolution of concepts, intermediate- and long-term clinical outcomes, study quality, and relevance. Older studies were included selectively if they were historically relevant or if data were scarce in recent publications. To facilitate evaluation of the quality of information provided, levels of evidence (LE) and grades of recommendation (GR) were inserted according to general principles of evidence-based medicine (EBM) (2).

2.2 Publication history
A first guidelines publication on upper urinary tract tumours was presented in 2004 (3). This document was updated and included in the EAU Guidelines compilation print in 2011. The current 2013 publication presents a limited update of the 2011 document.

This document was peer reviewed prior to publication.

2.3 Potential conflict of interest statement
The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

3. EVIDENCE SYNTHESIS

3.1 Epidemiology
Urothelial carcinomas are the fourth most common tumours after prostate (or breast), lung and colorectal cancer (4,5). They can be located in the lower urinary tract (bladder and urethra) or upper urinary tract (pyelocaliceal cavities and ureter). Bladder tumours account for 90-95% of urothelial carcinomas and are the most common malignancy of the urinary tract (1,5). However, UTUCs are uncommon and account for only 5-10% of urothelial carcinomas (4,6). The estimated annual incidence of UTUCs in western countries is about two new cases per 100,000 inhabitants. Pyelocaliceal tumours are about twice as common as ureteral tumours. In 17% of cases, concurrent bladder cancer is present (7). Recurrence of disease in the bladder occurs in 22-47% of UTUC patients (8-10), whereas recurrence in the contralateral upper tract is observed in 2-6% (11,12).

The natural history of UTUCs differs from that of bladder cancer: 60% of UTUCs are invasive at diagnosis compared with only 15-25% of bladder tumours (13,14). UTUCs have a peak incidence in people in their 70s and 80s, and they are three times more prevalent in men than in women (15,16).

There are familial/hereditary cases of UTUCs linked to hereditary non-polyposis colorectal carcinoma (HNPCC) (17). Among patients with UTUCs, HNPPC cases can be screened during a medical interview (18). There is a suspicion of hereditary UTUC if the patient is < 60 years of age, has a personal history of an HNPPC-associated cancer, a first-degree relative aged < 50 years with HNPPC-associated cancer, or two first-degree relatives with HNPPC-associated cancer (18). These patients should undergo DNA sequencing to identify hereditary cancers that have been misclassified as sporadic cancers by insufficient clinical data (19).
The presence of other HNPCC-associated cancers should also be evaluated. These patients should be closely monitored, and genetic counselling is advocated (17,19).

3.2 Risk factors

Many environmental factors contribute to the development of UTUCs (20,21). Some are similar to those associated with bladder cancer, whereas others are more specific for UTUC. Tobacco and occupational exposure remain the principal exogenous risk factors for developing these tumours. Exposure to tobacco increases the relative risk of developing UTUC from 2.5 to 7 (20,21). UTUC “amino tumours” are related to occupational exposure to certain aromatic amines. These aromatic hydrocarbons are used in many industries (e.g., dyes, textiles, rubber, chemicals, petrochemicals, and coal). They are responsible for the carcinogenicity of certain chemicals, including benzidine and β-naphthalene. These two chemicals have been banned since the 1960s in most industrialised countries. In most cases, UTUCs are secondary to an amino tumour of the bladder. The average duration of exposure needed to develop a UTUC is approximately 7 years, with a latency period of about 20 years following the termination of exposure. The estimated risk (odds ratio) of developing UC after exposure to aromatic amines is 8.3 (21,22).

Upper urinary tract tumours resulting from phenacetin consumption almost disappeared after the product was banned in the 1970s (21).

Although the incidence of Balkan endemic nephropathy is also on the decline, roles have been proposed for aristolochic acid and the consumption of Chinese herbs in the pathophysiology and induction, respectively, of this nephropathy (23-26). Several studies have revealed the carcinogenic potential of aristolochic acid contained in Aristolochia fangchi and Aristolochia clematitis (plants endemic to the Balkans). This acid contains a set of highly toxic nitrophenolate derivatives that exhibit a powerful mutagenic action due to their ability to make up covalent links with cell DNA. The aristolochic acid derivative d-aristolactam causes a specific mutation in the p53 gene at codon 139. This mutation is very rare in the non-exposed population and is predominant in patients with nephropathy due to Chinese herbs or Balkan endemic nephropathy who present with UTUC (21,23,24).

A high incidence of UTUC has also been described in Taiwan, especially in the population on the southwest coast of the island, and represents 20-25% of UCs in the region (21,24). The association of UTUC with blackfoot disease and arsenic exposure remains unclear in this patient population (21,24).

Differences in the ability to counteract carcinogens may contribute to host susceptibility and the risk of developing UC. Although it is not unusual that a genotype confers protection for an organ and increases the risk for another, UTUC may share some risk factors or molecular disruption pathways with bladder UC, but each has its own specific features. Certain genetic polymorphisms are associated with an increased risk of cancer or faster disease progression, thus, there is variability in inter-individual susceptibility to the risk factors just mentioned. Only two polymorphisms specific to UTUC have been reported so far (27,28). A variant allele, SULT1A1*2, which reduces sulfotransferase activity, and a polymorphism located at the T allele of rs9642880 on chromosome 8q24 enhance the risk of developing UTUC.

3.3 Histology and classification

3.3.1 Histological types

More than 95% of UCs are derived from the urothelium and correspond to UTUCs or bladder tumours (13,29). With regard to UTUCs, morphological variants have been described that are more often observed in urothelial kidney tumours. These variants always correspond to high-grade tumours, and such UCs are associated with one of the following variants: micropapillary, clear cell, neuroendocrine, and lymphoepithelial (29,30).

Collecting-duct carcinoma has similar characteristics to UTUC because of its common embryologic origin (31). Upper urinary tract tumours with pure non-urothelial histology are exceptions (32,33) but a variant can be seen in nearly 25% of cases (34). Squamous cell carcinomas of the upper urinary tract represent < 10% of pyelocaliceal tumours and are even rarer within the ureter. Squamous cell carcinoma of the urinary tract is associated with chronic inflammatory and infectious disease arising from stones in the urinary tract (29,30). Other histological subtypes are adenocarcinomas (< 1%), small cell carcinomas, and sarcomas.

3.3.2 Classification

The classification and morphology of UTUCs are similar to those of bladder carcinomas (13). It is possible to distinguish between non-invasive papillary tumours (papillary urothelial tumours of low malignant potential, low-grade papillary UC, high-grade papillary UC), flat lesions (carcinoma in situ (CIS)), and invasive carcinomas. All variants of urothelial tumours described in the bladder can also be observed in the upper urinary tract (34).

3.3.2.1 Tumour Node Metastasis staging

Table 1 presents the Union Internationale Contre le Cancer (UICC) 2009 Tumour Node Metastasis (TNM) classification used throughout these guidelines (35).
According to the TNM classification, the regional lymph nodes that should be considered are the hilar, abdominal para-aortic, and paracaval nodes, and, for the ureter, the intrapelvic nodes. Laterality does not affect the N classification.

There is an interest to use a renal pelvic pT3 subclassification to discriminate between microscopic infiltration of the renal parenchyma (pT3a) versus macroscopic infiltration or invasion of peripelvic adipose tissue (pT3b) (34,36). pT3b UTUCs are more likely to have aggressive pathological features and have a higher risk of recurrence (34,36).

*All EAU guidelines advocate the TNM system of tumour classification.

3.3.2.2 Tumour grade

Until 2004, the most common classification used was the World Health Organization (WHO) classification of 1973, which distinguished only three grades (G1, G2 and G3) (37). In recent years, molecular biological data have allowed for further distinction between different tumour groups and the development of a new classification system that better reflects the potential growth of these tumours (38). Thus the 2004 WHO classification now takes histological data into account to distinguish among three groups of non-invasive tumours: papillary urothelial neoplasia of low malignant potential; low-grade carcinomas; and high-grade carcinomas. There are almost no tumours of low malignant potential in the upper urinary tract (29,30).

3.4 Symptoms

The diagnosis of UTUC may be fortuitous or related to the exploration of symptoms. The symptoms are generally restricted (39). The most common symptom of UTUC is gross or microscopic haematuria (70-80%) (40). Flank pain occurs in 20-40% of cases, and a lumbar mass is present in 10-20% (41,42). However, systemic symptoms (altered health condition including anorexia, weight loss, malaise, fatigue, fever, night sweats, or cough) associated with UTUC should prompt consideration of a more rigorous metastatic evaluation (41,42).

3.5 Diagnosis

3.5.1 Imaging

3.5.1.1 Computed tomography urography

Computed tomography (CT) urography is the imaging technique with the highest diagnostic accuracy for
UTUC and has replaced intravenous excretory urography and ultrasonography as the first-line imaging test for investigating high-risk patients (40). The sensitivity of CT urography for UTUC is reported to range from 0.67 to 1.0 and specificity from 0.93 to 0.99 depending on the technique used (43-50). Attention to technique is therefore very important for optimum results.

Computed tomography urography of the urinary tract acquires at least one image series during the excretory phase, usually 10-15 min, following the administration of intravenous contrast medium (51). Rapid acquisition of thin sections allows high-resolution isotropic images to be produced that can be viewed in multiple planes to assist with diagnosis without degradation of resolution (52,53).

Computed tomography urography can also detect wall thickening of the renal pelvis or ureter, which is a sign of UTUC, even when there is no luminal mass effect, but flat lesions are not detectable unless they exert a mass effect or cause urothelial thickening (54). The secondary sign of hydronephrosis on imaging in the presence of UTUC is associated with advanced pathological disease and poorer oncological outcomes (51,55).

3.5.1.2 Magnetic resonance imaging
Magnetic resonance (MR) urography is indicated in patients who cannot undergo CT urography usually when radiation or iodinated contrast media are contraindicated (56). The sensitivity of MR urography is 75% after contrast injection for tumours < 2 cm (56). Magnetic resonance urography with certain gadolinium-based contrast media is contraindicated in selected patients with severe renal impairment (< 30 ml/min creatinine clearance), due to the risk of nephrogenic systemic fibrosis.

Computed tomography urography is generally preferred to MR urography for diagnosing UTUCs in terms of greater diagnostic accuracy, lower cost, and greater patient acceptability.

3.5.2 Cystoscopy and urinary cytology
Positive urine cytology is highly suggestive of UTUC when bladder cystoscopy is normal and if CIS of the bladder or prostatic urethra has been largely excluded (e.g., by biopsies of any suspicious lesion, possibly guided by photodynamic diagnosis) (13,57). Cytology is less sensitive for UTUC than for bladder tumours, even for high-grade lesions, and it should ideally be performed in situ (i.e., in the renal cavities) (58). Retrograde ureteropyelography (through a ureteral catheter or during ureteroscopy) remains an option for the exclusion of a tumour in the upper urinary tract (44,59). However, urinary cytology of the renal cavities and ureteral lumina should preferably be performed prior to application of larger amounts of contrast agent for retrograde ureteropyelography, because it may deteriorate cytological specimens.

The sensitivity of fluorescence in situ hybridisation (FISH) for the identification of molecular abnormalities characterising UTUCs parallels its performance in bladder cancer; however, the preponderance of low-grade recurrent disease in the population undergoing surveillance and minimally-invasive therapy for UTUCs may limit its usefulness (60,61). In addition, FISH appears to have limited value for upper UTUCs surveillance (60,61).

3.5.3 Diagnostic ureteroscopy
Flexible ureteroscopy is used to visualise and biopsy the ureter, renal pelvis and collecting system with a technical success approaching 95%. Such ureteroscopic biopsies can determine tumour grade in 90% of cases with a low false-negative rate regardless of the size of the sample (62). Undergrading may occur from the diagnostic biopsy, making intensive follow-up a requirement if renal sparing treatments are selected (63). Ureteroscopy also facilitates selective ureteral sampling for cytology in situ (59,64,65).

Flexible ureteroscopy is especially useful when there is diagnostic uncertainty, when conservative treatment is being considered, or in patients with a solitary kidney. If available, ureteroscopy and biopsy should be performed in the preoperative assessment of any UTUC patient. Combining ureteroscopic biopsy grade, diagnostic imaging findings such as hydronephrosis, and urinary cytology may help decision making on radical nephroureterectomy (RNU) versus endoscopic treatment (64,66).

Technical developments in flexible ureteroscopes and the use of novel imaging techniques improve visualisation and diagnosis of flat lesions. Narrow band imaging appears to be the most promising technique but results are still preliminary (66,67). Table 2 lists the recommendations.

3.6 Prognostic factors
UTUCs that invade the muscle wall usually have a very poor prognosis. The 5-year specific survival is < 50% for pT2/pT3 and < 10% for pT4 (67,68). This section briefly describes the currently recognised prognostic factors (69).

3.6.1 Tumour stage and grade
According to the most recent classifications, the primary recognised prognostic factors are tumour stage and grade (64,69-71). Extranodal extension appears to be a powerful predictor of clinical outcomes in patients with UTUCs and positive lymph node metastases (72).

3.6.2 Age and sex
Sex is no longer considered an independent prognostic factor that influences UTUC mortality (15,69,73). Conversely, patient age is still considered an independent prognostic factor because older age at the time of RNU is associated with decreased cancer-specific survival (LE: 3) (69,74). However, chronologic age alone should not be an absolute exclusion criterion for the treatment of potentially curable UTUC but rather overall life expectancy. A significant proportion of elderly patients can still be cured with RNU (74). This suggests that chronological age alone is an inadequate indicator of outcomes in older UTUC patients (74,75).

3.6.3 Ethnicity
There are differences in clinicopathological characteristics of tumours between Caucasian and Japanese patients. However, race and ethnicity are not so far recognised as independent factors for survival (LE: 3) (76).

3.6.4 Tumour location
According to the most recent findings, the initial location of the tumour within the upper urinary tract (e.g., ureter vs. renal pelvis) is a prognostic factor (77-79) (LE: 3). There is a prognostic impact of tumour location when adjusted for tumour stage: ureteral and multifocal tumours have a worse prognosis than renal pelvic tumours (69,78-80).

3.6.5 Tobacco consumption
Smoking intensity (long-term exposure) and being a smoker at diagnosis increases the risk for poor oncological outcomes (LE: 3) (81-83).

3.6.6 Lymphovascular invasion
Lymphovascular invasion is present in approximately 20% of UTUCs and an independent predictor of survival (84,85). Lymphovascular invasion status should be systematically included and specifically reported in the pathologic report of all RNU specimens (LE: 3) (84,86).

3.6.7 Surgical margins
Positive surgical margin after RNU appears to be a significant factor for developing subsequent UTUC metastases (LE: 3). Pathologists should look for, and report on, positive margins at the level of ureter transsections, bladder cuff and around the tumour if the tumour is ≥ T2. (87).

3.6.8 Other factors
Extensive tumour necrosis is an independent predictor of clinical outcomes in patients who undergo RNU. Extensive tumour necrosis can be defined as > 10% of the tumour area (LE: 3) (88,89).

The tumour architecture (e.g., papillary vs. sessile) of UTUCs appears to be associated with the prognosis after RNU. A sessile growth pattern is associated with the worst outcomes (LE: 3) (90,91).

The presence of concomitant CIS in patients with organ-confined UTUC is associated with a higher
risk of recurrent disease and cancer-specific mortality (LE: 3) (92,93). Similar to lower tract urothelial carcinoma, concomitant CIS is an independent predictor of worse outcomes in organ-confined disease (94). A previous history of bladder CIS is associated with increased risk of recurrence and death from UTUCs (LE: 3) (95).

The American Society of Anesthesiologists (ASA) score also significantly correlates with cancer-specific survival after RNU (LE: 3) (96) but ECOG performance status correlates only with overall survival (97). Obesity and higher body mass index adversely affect cancer-specific outcomes in patients with UTUCs (LE: 3) (98).

3.6.9 Molecular markers

Several research groups are working on UTUC characteristics and carcinogenesis pathways. Several studies have investigated the prognostic impact of various tissue-based markers that are related to cellular processes such as cell adhesion (E-cadherin and CD24), cell differentiation (Snail and epidermal growth factor receptor) angiogenesis (hypoxia-inducible factor-1α and metalloproteinases), cell proliferation (Ki67), epithelial-mesenchymal transition (snail), mitosis (Aurora-A), apoptosis (Bcl-2 and survivin) and vascular invasion (récepteur d’origine nantais RON) and c-met protein MET) (69,99-102). However, because of the rarity of the disease, the main limitations shared by these studies are their retrospective nature and their small sample size.

Microsatellite instability (MSI) is an independent molecular marker used for tumour prognosis (103). In addition, MSI can help detect germ-line mutations, allowing for the detection of possible hereditary cancers (17).

To date, none of the markers has fulfilled the clinical and statistical criteria necessary to support their introduction in daily clinical decision making.

3.7 Prediction and risk stratification

Available accurate predictive tools are rare in UTUCs.

There are two available models in a preoperative setting: one for the prediction of locally advanced cancer that could guide the extent of lymph node dissection at the time of RNU (104); and one for selection of non-organ-confined UTUCs that are likely to benefit from nephroureterectomy (105).

Additionally there are two nomograms that can predict survival rates in a postoperative setting based on standard pathological features: one coming from an international group (106) and the other one built from a European population only (107).

3.8 Treatment

3.8.1 Localised disease

3.8.1.1 Radical nephroureterectomy

Radical nephroureterectomy with excision of the bladder cuff is the gold standard treatment for UTUC, regardless of the location of the tumour in the upper urinary tract (LE: 3) (14). The RNU procedure must comply with oncological principles, which consist of preventing tumour seeding by avoiding entry into the urinary tract during tumour resection (14). Resection of the distal ureter and its orifice is performed because it is a part of the urinary tract with considerable risk of tumour recurrence. After removal of the proximal part, it is almost impossible to image or approach it by endoscopy during follow-up. Recent publications on survival after RNU have concluded that removal of the distal ureter and bladder cuff is beneficial (108-110).

McDonald et al. presented the pluck technique in 1952, but it was not until 1995 (111) that the usefulness of an endoscopic approach to the distal ureter was emphasised, and then several other alternative techniques were reconsidered to simplify resection of the distal ureter: stripping, transurethral resection of the intramural ureter, and intussusception techniques (11,109). Apart from ureteral stripping, none of these techniques is inferior to excision of the bladder cuff (LE: 3) (74-76,78). Nevertheless, the endoscopic approach is clearly associated with a higher risk of subsequent bladder recurrence (112).

A delay between diagnosis and removal of the tumour may increase the risk of disease progression. However the cut-off has been disputed between 45 days and 3 months and it remains a moot point (LE: 3) (113-115).

Lymph node dissection (LND) associated with RNU is of therapeutic interest and allows for optimal staging of the disease (LE: 3) (116,117). However, the anatomical sites of LND have not yet been clearly defined. The LND template is likely to have a greater impact on patient survival than the number of lymph nodes removed (118).

Lymph node dissection appears to be unnecessary in cases of TaT1 UTUCs because it was reported to be retrieved in 2.2% T1 versus 16% pT2-4 tumours (117). In addition, a continuous increase in the probability of lymph-node-positive disease related to pT classification has been described (117). However, these data are retrospective; consequently, under-reporting of the true rate of node-positive disease is likely. It is not yet possible to standardise either indication or extent of LND. However, LND can be achieved according to lymphatic drainage as follows: LND medially to the ureter in ureteropelvic tumour, retroperitoneal LND in
case of higher ureteral tumour and/or tumour of the renal pelvis (i.e., right side: border vena cava and left side: border aorta) (116-118).

The laparoscopic RNU has not yet achieved final proof of its safety. There are early reports of retroperitoneal metastatic dissemination and dissemination along the trocar pathway when large tumours were manipulated in a pneumoperitoneal environment (119,120).

Several precautions must be taken when operating with a pneumoperitoneum because it may increase tumour spillage:

• Entering the urinary tract should be avoided.
• Direct contact of the instruments with the tumour should be avoided.
• Laparoscopic RNU must take place in a closed system. Morcellation of the tumour should be avoided, and an endobag is necessary to extract the tumour.
• The kidney and ureter must be removed en bloc with the bladder cuff.
• Invasive or large (T3/T4 and/or N+/M+) tumours are contraindications for laparoscopic RNU, until proven otherwise.

Recent data show a tendency towards equivalent oncological outcomes after either laparoscopic or open RNU (121-126). In addition, the laparoscopic approach appears to be superior to open surgery only with regard to functional outcomes (LE: 3) (121-126). Only one prospective randomised study of 80 patients has provided evidence that laparoscopic RNU is not inferior to open RNU for non-invasive UTUC (LE: 2) (127). In addition, it has been demonstrated that oncological outcomes after RNU have not changed significantly over the past three decades despite staging and surgical refinements (LE: 3) (128). Recommendations are listed in Table 3.

#### 3.8.1.2 Conservative surgery

Conservative surgery for low-risk UTUCs allows preservation of the upper urinary renal unit while sparing the patient the morbidity associated with open radical surgery. Conservative management of UTUCs can be considered in imperative cases (renal insufficiency or solitary functional kidney) or in elective cases (when the contralateral kidney is functional) for low-grade, low-stage tumours (LE: 3) (110,129,130). The choice of technique depends on technical constraints, the anatomical location of the tumour, and the experience of the surgeon.

##### 3.8.1.2.1 Ureteroscopy

Endoscopic ablation can be considered in highly selected cases and in these situations (131-133):

- A flexible rather than a rigid ureteroscope, laser generator (134), and pliers (pluck) for biopsies are available (LE: 3) (132,135).
- The patient is informed of the need for closer, more stringent surveillance.
- A complete resection of the tumour is strongly advocated.

However there is a risk of understaging and undergrading the disease with pure endoscopic management.

##### 3.8.1.2.2 Segmental resection

Segmental ureteral resection with wide margins provides adequate pathological specimens for definitive staging and grade analysis while also preserving the ipsilateral kidney. Ureteroureterostomy is indicated for non-invasive, low-grade tumours of the proximal ureter or mid-ureter that cannot be removed completely by endoscopic means (i.e., size or multiplicity) and for high-grade or invasive tumours when renal sparing surgery
(RSS) for preservation of renal function is a goal (LE: 3). High-grade tumours of the proximal ureter or mid-ureter should undergo RNU with excision of bladder cuff when possible. Complete distal ureterectomy and neocystostomy is indicated for non-invasive, low-grade tumours in the distal ureter that cannot be removed completely by endoscopic means (i.e., size or multiplicity) and for high-grade, locally-invasive tumours (LE: 3) (136-138). For both ureteroureterostomy and complete distal ureterectomy and neocystostomy it is necessary, however, to ensure that the area of tissue around the tumour is not invaded. Segmental resection of the iliac and lumbar ureter is associated with a failure rate greater than that for the distal pelvic ureter (136-138). Open resection of tumours of the renal pelvis or calices has almost disappeared. Resection of pyelocaliceal tumours is technically difficult, and the recurrence rate is higher than for tumours of the ureter.

### 3.8.1.2.3 Percutaneous access

Percutaneous management can be considered for low-grade or non-invasive UTUCs in the renal cavities (LE: 3) (132,139,140). This treatment option may be offered to patients with low-grade tumours in the lower caliceal system that are inaccessible or difficult to manage by ureteroscopy. A theoretical risk of seeding exists in the puncture tract and in perforations that may occur during the procedure. This approach, however, is being progressively abandoned due to enhanced materials and advances in distal-tip deflection of recent ureteroscopes (132,139,140).

### 3.8.1.3 Adjuvant topical agents

The antegrade instillation of bacillus Calmette-Guérin vaccine or mitomycin C in the upper urinary tract by percutaneous nephrostomy via a three-valve system open at 20 cm (after complete eradication of the tumour) is technically feasible after conservative treatment of UTUCs or for the treatment of CIS (LE:3) (141). Retrograde instillation through a ureteric stent or with the help of the reflux obtained from a double J stent have also been used (142), but it can be dangerous due to possible ureteric obstruction and consecutive pyelovenous influx during instillation/perfusion. The medium-term results are similar to those observed for the treatment of bladder tumours but have not been confirmed in long-term studies (LE: 3) (141,142).

One prospective randomised study of 144 patients has provided evidence that a single postoperative dose of intravesical mitomycin reduces the risk (i.e., absolute risk 11%) of a bladder tumour within the first year following RNU (LE: 2) (143). Table 4 lists the recommendations.

#### 3.8.2 Advanced disease

##### 3.8.2.1 Nephroureterectomy

There are no benefits of RNU in metastatic (M+) disease, although it can be considered a palliative option (LE: 3) (14,117).

##### 3.8.2.2 Chemotherapy

UTUCs are urothelial tumours, therefore, platinum-based chemotherapy is expected to produce similar results.
to those seen in bladder cancer. Several platinum-based chemotherapy regimens have been proposed (144). However, adding chemotherapy-related toxicity, particularly nephrotoxicity from platinum derivatives, to a population with already impaired postsurgical renal function may also be related to the reduced survival in these patients (145,146). In addition, not all the patients receive this treatment because of comorbidity and impaired renal function after radical surgery.

Contrary to what has been demonstrated for bladder cancer, there have been no reported effects of neoadjuvant chemotherapy for UTUCs in the only study published to date (147). Although survival data need to mature and longer follow-up is awaited, current preliminary data provide justification for the sustained support of trials using this strategy in UTUCs.

Adjuvant chemotherapy can somehow achieve a recurrence-free rate of up to 50% but has clearly no impact on survival (148,149). Further data are awaited from the ongoing prospective randomised POUT trial (PeriOperative chemotherapy or sUrveillance in upper Tract urothelial cancer) (150). Data are currently insufficient to provide any recommendations.

3.8.2.3 Radiotherapy

Adjuvant radiotherapy may improve local control of the disease (151). When given in combination with cisplatinum, it may result in longer disease-free and overall survival (152) (LE: 3). Radiotherapy appears to be scarcely relevant nowadays both as a unique therapy and associated with chemotherapy as adjuvant therapy (Fig. 1).

Fig. 1: Proposed flowchart for the management of UTUC

MDCT = multidetector computed tomography

3.9 Follow-up

Stringent follow-up of UTUC patients after surgical treatment is mandatory to detect metachronous bladder tumours (in all cases), local recurrence, and distant metastases (in the case of invasive tumours).

When RNU is performed, local recurrence is rare, and the risk of distant metastases is directly related to the risk factors listed previously. The reported recurrence rate within the bladder after treatment of a primary UTUC varies considerably from 22 to 47% (8,10). Thus, the bladder should be observed in all cases.
The surveillance regimen is based on cystoscopy and urinary cytology for at least 5 years (8-10). Bladder recurrence should not be considered as distant recurrence. When conservative treatment is performed, the ipsilateral upper urinary tract requires careful follow-up due to the high risk of recurrence (129,133,135). Despite notable improvements in endourological technology, the follow-up of patients treated with conservative therapy is difficult, and frequent and repeated endoscopic procedures are necessary.

Table 5 lists the recommended follow-up schedules.

</tr>
</tbody>
</table>

**4. CONCLUSIONS**

These renewed UTUC guidelines contain information for the diagnosis and treatment of individual patients according to a current, standardised approach. When determining the optimal treatment regimen for their patients, urologists must take into account each individual patient’s specific clinical characteristics with regard to renal function including medical comorbidity; tumour location, grade, and stage; and molecular marker status.

1. INTRODUCTION

1.1 The guideline

The European Association of Urology (EAU) Guidelines Panel for Muscle-invasive and Metastatic Bladder Cancer (MIBC) has prepared these guidelines to help urologists assess the evidence-based management of MIBC and to incorporate guideline recommendations into their clinical practice. The EAU Guidelines Panel comprises an international multidisciplinary group of experts from the fields of urology, pathology, radiology and oncology.

It is evident that optimal treatment strategies for MIBC require the involvement of a specialist multidisciplinary team and a model of integrated care to avoid fragmentation of patient care.

The Muscle-invasive and Metastatic Bladder Cancer guidelines are one of four EAU guidelines documents addressing bladder cancer (EAU Guidelines on Non-muscle-invasive (TaT1 and CIS) Bladder Cancer, EAU Guidelines on Upper Urinary Tract Urothelial Cell Carcinomas and EAU Guidelines on Primary Urethral Carcinoma) which, together, present a comprehensive overview of the management of urothelial neoplasms (1-3).

1.2 Methodology

1.2.1 Data identification

Comprehensive literature searches were designed for each section of the MIBC guidelines with the help of an expert external consultant. Following detailed internal discussion, searches were carried out in the Cochrane Library database of Systematic Reviews, the Cochrane Library of Controlled Clinical Trials, and Medline & Embase on the Dialog-Datastar platform. The searches used the controlled terminology of the respective databases. Both Medline and EMTREE were analysed for relevant terms; urinary bladder neoplasms (Medline) and bladder cancer (Embase) were the narrowest single terms available.

Extensive use of free text ensured the sensitivity of the searches, although the subsequent concomitant workload for panel members having to assess the substantial body of literature greatly increased.

Search strategies covered the last 10 years for Medline and for Embase in most cases. Randomised controlled trial (RCT) strategies used were based on Scottish Intercollegiate Guidelines Network (SIGN) and Modified McMaster/Health Information Research Unit (HIRU) filters for RCTs, systematic reviews and practice guidelines on the OVID platform. Results of all searches were scan-read by panel members. In many cases there was a high ‘numbers needed to read’ due to the sensitivity of the search.

There is clearly a need for continuous re-evaluation of the information presented in the current guidelines by an expert panel. It must be emphasised that these guidelines contain information for the treatment of an individual patient according to a standardised approach.

The level of evidence (LE) and grade of recommendation (GR) provided in this guideline follow the listings in Tables 1 and 2 (4). The aim of grading the recommendations is to provide transparency between the underlying evidence and the recommendation given.

It should be noted, however, that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (5-7).

The EAU Guidelines Office do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

1.2.2 Publication history

The EAU published the first guidelines on bladder cancer in 2000. This document covered both superficial (non-muscle-invasive) bladder cancer and MIBC. As different treatment strategies are employed for these
conditions it was decided to split these topics up, resulting in a first publication of the MIBC guidelines in 2004, with subsequent updates in 2007, 2009, 2010, 2011, 2012 and this 2013 update. A quick reference document presenting the main findings is also available alongside several scientific publications (8-10).

All texts can be viewed and downloaded for personal use at the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

1.3 Summary of updated information
For this 2013 update, of note are the following changes:

Chapter 2 “Epidemiology and risk factors”;
• Section 2.2.8 Carcinoma in situ has been added.

Chapter 3 “Classification”;
• Sections 3.3, through 3.3.5 were revisited resulting in slightly adapted recommendations in section 3.3.4 (recommendations for the assessment of tumour specimens).
• Section 3.3.5 (pT2 substaging in node-negative disease after cystectomy) has been added.

Chapter 4 “Diagnosis and staging”;
• Sections 4.2.1.2 (CT imaging for local staging of MIBC), 4.2.2 (Imaging of lymph nodes in MIBC) and 4.2.3 (Upper urinary tract urothelial carcinoma) have been added, as well as section 4.2.5 (Future developments).

Chapter 6 “Neoadjuvant Chemotherapy”;
• A new section 6.2 (The role of imaging to assess treatment response) has been included. The text has been updated with new literature resulting in amended conclusions and recommendations (section 6.4).

Chapter 7 “Radical Surgery and Urinary Diversion”
• A new section 7.1.4 (MIBC and comorbidity) on co-morbidities and patient selection for orthotopic diversion has been added.

Chapter 12 “Metastatic disease”;
• New data has been added, in particular to section 12.3 (Standard first-line chemotherapy for “fit” patients).

Chapter 14 “Follow-up”;
• Additional data included on recurrences and secondary urethral tumours.

For all updated sections, the literature has been assessed for currency.

Updates of chapters 5 - 8 - 9 - 10 - 11 and 13 are foreseen for publication in 2014.

2. EPIDEMIOLOGY AND RISK FACTORS

2.1 Epidemiology
Bladder cancer is the ninth most common cancer diagnosis worldwide, with more than 330,000 new cases each year and more than 130,000 deaths per year, with an estimated male-female ratio of 3.8:1.0 (1). At any point in time, 2.7 million people have a history of urinary bladder cancer (1).

At the initial diagnosis of bladder cancer, 70% of cases are diagnosed as non-muscle-invasive bladder cancer (NMIBC) and approximately 30% as muscle-invasive bladder cancer (MIBC). Among patients treated with radical cystectomy because of MIBC, 57% had muscle invasion at presentation, while 43% were initially diagnosed with NMIBC that progressed despite organ-preserving treatment (2). Approximately one-third of patients diagnosed with MIBC have undetected metastases at the time of treatment for the primary tumour (3), while 25% of patients who undergo radical cystectomy present with lymph node involvement at the time of surgery.
2.2 Risk factors for bladder cancer

2.2.1 Tobacco smoking

Tobacco smoking is the most well-established risk factor for bladder cancer, causing 50-65% of male cases and 20-30% of female cases (4). A causal relationship has been established between exposure to tobacco and cancer in studies in which chance, bias, and confounding can be ruled out with reasonable confidence (5).

The incidence of bladder cancer is directly related to the duration of smoking and the number of cigarettes smoked per day (6). The risk of bladder cancer is also higher in those who start smoking at a young age or who are exposed to environmental tobacco smoke during childhood (7). A recent meta-analysis looked at 216 observational studies on cigarette smoking and cancer from 1961 to 2003, with reported estimates for current and/or former smokers. The pooled risk estimates for bladder cancer demonstrated a significant association for both current and former smokers. In an analysis of 21 studies, the overall relative risk calculated for current smokers was 2.77 (95% confidence interval [CI], 2.17 to 3.54), while an analysis of 15 studies showed that the overall relative risk calculated for former smokers was 1.72 (95% CI, 1.46 to 2.04) (8). An immediate decrease in the risk of bladder cancer was observed in those who stopped smoking. The reduction was about 40% within 1-4 years of quitting smoking and 60% after 25 years of cessation (6). Encouraging people to stop smoking would result in the incidence of bladder cancer decreasing equally in men and women.

2.2.2 Occupational exposure to chemicals

Occupational exposure is the second most important risk factor for bladder cancer. Work-related cases have accounted for 20-25% of all bladder cancer cases in several series. The substances involved in chemical exposure have been benzene derivatives and aryl amines (2-naphthylamine, 4-ABP, 4,4′-methyleneedianiline, and o-toluidine), and it is likely to occur in occupations in which dyes, rubbers, textiles, paints, leathers, and chemicals are used (9). The risk of bladder cancer due to occupational exposure to carcinogenic aromatic amines is significantly greater after 10 years or more of exposure; the mean latency period usually exceeds 30 years (10,11). The chemicals involved have contributed minimally to the current incidence of bladder cancer in Western countries because of strict regulations. In fact, there has been a trend towards a decrease in bladder cancer due to occupational exposure, as indicated by a pooled analysis of 11 European case-control studies on bladder cancer between 1976 and 1996 (12).

An example of occupational exposure is that of aromatic amines. These are established carcinogens for urothelium and can be inactivated by a metabolic acetylation pathway. The presence of an NAT2 slow-acetylation genotype has been associated with a higher risk of bladder cancer (13), suggesting that patients who are slow acetylators may be more susceptible to bladder cancer than rapid acetylators. Other risk factors include phenacetin, which the International Agency for Research on Cancer (IARC) included in 1987 among proven human carcinogens. Some studies have suggested that the risk of bladder cancer due to phenacetin is dose-dependent; however, the data concerning its metabolite acetaminophen are controversial (14).

2.2.3 Radiotherapy

Increased rates of secondary bladder malignancies have been reported after external-beam radiotherapy (EBRT) for gynaecological malignancies, with relative risks of 2-4 (15). A recent population cohort study identified 243,082 men treated for prostate cancer between 1988 and 2003 in the Surveillance, Epidemiology and End Results database (SEER) in the USA. The standardised incidence ratios for bladder cancer developing after radical prostatectomy (RP), EBRT, brachytherapy (BT), and EBRT-BT were 0.99, 1.42, 1.10, and 1.39, respectively, in comparison with the general U.S. population. The increased risk of bladder cancer in patients undergoing ERBT, BT, or ERBT-BT should be taken into account during follow-up, although the likelihood of mortality was described as very low in a recent study (16). It has recently been proposed that patients who have received radiotherapy for prostate cancer with modern modalities such as intensity-modulated radiotherapy (IMRT) may have lower rates of in-field bladder and rectal secondary malignancies (17). Nevertheless, since longer follow-up data are not yet available, and as bladder cancer requires a long period to develop, patients treated with radiation and with a long life-expectancy are at highest risk and should be followed up closely (17).

2.2.4 Dietary factors

Several dietary factors have been considered to be related to bladder cancer; however, the links remain controversial. Currently, there is limited evidence of a causal relationship between bladder cancer and dietary factors. A meta-analysis of 38 articles reporting data on diet and bladder cancer supported the hypothesis that vegetable and fruit intake reduces the risk of bladder cancer (18). For bladder cancer, there appears to be no association between dietary transfatty acid (TFA) intake and an increased risk, as observed for prostate cancer (19).
2.2.5 **Bladder schistosomiasis**

Bladder schistosomiasis (bilharzia) is the second most common parasitic infection after malaria, with about 600 million people exposed to infection in Africa, Asia, South America, and the Caribbean (20). Although there is a well-established relationship between squamous cell carcinoma of the bladder and schistosomiasis, the trends are changing for bladder cancer in endemic zones such as Egypt. Data from the National Cancer Institute (NCI) in Cairo, the largest tertiary cancer hospital in Egypt, showed that patients diagnosed in 2005 had a six-fold higher chance of developing urothelial carcinoma in comparison with patients diagnosed in 1980 (21). This shift from squamous cell carcinoma to urothelial carcinoma is attributed to a decline in the detection of bilharzia eggs in urine samples, probably due to better control of the disease in rural populations (22,23).

2.2.6 **Chronic urinary tract infection**

Muscle-invasive bladder cancer, particularly invasive squamous cell carcinoma, has been linked to the presence of chronic urinary tract infection (UTI) distinct from schistosomiasis. A direct association between bladder cancer and UTIs has been observed in several case-control studies, which have reported a twofold increased risk of bladder cancer in patients with recurrent UTIs in some series. However, some of these results may be attributed to recall bias (24). Furthermore, to date, no clear relationship between any bacterial or viral infection and bladder cancer has been established in prospective studies (25). However, an increased risk of bladder cancer has been described in patients with long-term indwelling catheters (26).

2.2.7 **Chemotherapy**

The use of cyclophosphamide, an alkylating agent used to treat lymphoproliferative diseases and other nonneoplastic diseases, has been correlated with subsequent development of MIBC, with a latency period of 6-13 years. Acrolein is a metabolite of cyclophosphamide and is responsible for the increase in the incidence of bladder cancer. This effect occurs independently of the association of haemorrhagic cystitis with the same treatment (27,28) and was counteracted with concomitant application of mercaptog-ethanesulfonate (MESNA) (29).

2.2.8 **Synchronous and metachronous upper urinary tract tumours**

In some cases, there is an association between upper tract urothelial carcinoma (UTUC) and bladder cancer. The incidence of UTUC after a diagnosis of NMIBC has been reported to be between 1.7% and 26%. Although synchronous UTUC and NMIBC are uncommon, 46% of UTUCs are invasive.

In a retrospective review of 1,529 patients with primary non-muscle-invasive bladder carcinoma who underwent initial examination of the upper urinary tract with excretory urography, those with a tumour in the bladder trigone were almost six times more likely to develop a synchronous tumour in the upper urinary tract (30). Examination of the upper urinary tract alone in patients with a tumour in the trigone or with multiple bladder tumours was capable of diagnosing 41% or 69% of UTUCs, respectively. In multiple and high-risk tumours, there is an increased risk of tumour recurrence in the upper urinary tract. Carcinoma in situ (CIS) in the bladder is an important risk factor for subsequent upper urinary tract recurrence (31). As well, it has been shown in various studies that tumour involvement of the distal ureter at RC is an independent risk factor for metachronous upper urinary tract (mUUT) recurrence (32,33), with an approximately 2.6-fold increase in the relative risk (33).

In addition, the overall incidence of bladder cancer developing after treatment for UTUC has been reported in the literature as 15-50%. Level 1 evidence from prospective randomised trials is not yet available. Intraluminal tumour seeding and pan-urothelial field change effects have both been proposed to explain intravesical recurrences. In most cases, bladder cancer arises in the first 2 years after UTUC management. However, the risk is lifelong, and repeat episodes are common. No variables can be used to predict future bladder cancer recurrence in UTUC patients reliably. A history of bladder cancer prior to UTUC management and upper tract tumour multifocality are the only commonly reported clinical risk factors in the current literature (34).

2.2.9 **Gender**

In a retrospective study of patients who had undergone radical cystectomy, it was found that women were more likely to be diagnosed with primary muscle-invasive disease than men (85% vs. 51%) (2). It has been suggested that women are more likely to be older than men when diagnosed, with a direct effect on their survival. In addition, delayed diagnosis is more likely in women after haematuria is observed, as the differential diagnosis in women includes diseases that are more prevalent than bladder cancer (35).

Differences in the gender prevalence of bladder cancer may be due to other factors besides tobacco and chemical exposure. In a large prospective cohort study, postmenopausal status was associated with an
increase in bladder cancer risk even after adjustment for smoking status. This result suggests that the
differences in oestrogen and androgen levels between men and women may be responsible for some of the
difference in the gender prevalence of bladder cancer (36-38). Recently, a study of Egyptian women found that
younger age at menopause (< 45 y) was a factor associated with an increasing risk of bladder cancer, while
multiple pregnancies and use of oral contraceptives were associated with decreased odds of having bladder
cancer. The strength of the associations was greater in the urothelial carcinoma group (39). A recent publication
mentions that female gender has a significant negative impact on cancer-specific survival in patients who are
younger and have lymphovascular invasion, possibly suggesting different clinical phenotypes (40).

2.2.10 Ethnic and socioeconomic status
There are limited data on this topic, but a study based on 13,234 cases diagnosed in the SEER database in
the period 1979-2003 showed that the survival time from diagnosis was significantly lower among cancer
cases in patients with low socioeconomic status (SES) compared with those with higher SES. Hazard ratios
for all causes and cancer-specific mortality among blacks in comparison with whites for eight of the most
common types of cancer combined lost statistical significance after adjustment for SES factors and treatments.
However, blacks still had unfavourable prognoses in comparison with whites even after adjustment for SES and
treatment for tumours such as breast, colorectal, and urinary bladder cancer (41).

3. CLASSIFICATION

3.1 Tumour, node, metastasis classification

The tumour, node, metastasis (TNM) classification of malignant tumours is the method most widely used to classify the extent of cancer spread. Recently, a seventh edition was published, effective as of 2010 (1 (Table 3). There are no significant modifications in it for bladder cancer in comparison with the previous edition (2002).

3.2 Histological grading of non-muscle-invasive bladder tumours

A new classification of noninvasive urothelial tumours was proposed by the World Health Organization (WHO) and the International Society of Urological Pathology (ISUP) in 1998. It was published by the WHO in 2004 (2,3) (see table below). Its major contribution is a detailed histological description of the various grades using specific cytological and architectural criteria. A web site (http://www.pathology.jhu.edu/bladder) illustrating examples of various grades has been developed to improve accuracy in using the system.

</tr>
</tbody>
</table>

3.2.1 WHO grading

The 2004 WHO grading differentiates between papilloma, papillary urothelial neoplasms of low malignant potential (PUNLMP), and low-grade and high-grade urothelial carcinomas.
Papilloma is composed of a delicate fibrovascular core covered by normal urothelium. PUNLMP is defined as a papillary fibrovascular growth covered with proliferated urothelium, exceeding the normal thickness. Although PUNLMPs have a negligible risk of progression, they are not completely benign and have a tendency to recur (3b). The low-grade papillary urothelial carcinoma group includes the majority of former grade 1 (WHO 1973) cases and some former grade 2 cases (if there is variation in the architectural and cytological features at high magnification).

Use of the 2004 WHO classification is recommended, as this should result in a uniform diagnosis of tumours better classified according to their risk potential. However, until the 2004 WHO classification has been validated by further clinical trials, tumours should be graded using both the 1973 and the 2004 WHO classifications (4). Most clinical trials published so far on bladder tumours have been performed using the 1973 WHO classification, so this is used in the 2013 edition of the guidelines.

3.3 Pathology
3.3.1 Handling of specimens by urologists
In transurethral resection (TUR) specimens, the superficial and deep areas of the tumour must be sent to the pathology laboratory separately. If random biopsies of the flat mucosa have been carried out, each biopsy of the flat mucosa must also be sent separately.

In radical cystectomy, bladder fixation must be carried out as soon as possible. The pathologist must open the specimen from the urethra to the bladder dome and fix the specimen in formalin. In some circumstances, this procedure can also be performed by the urologist. In a female cystectomy specimen, the length of the urethral segment removed en bloc with the specimen should be checked, preferably by the urological surgeon (5).

3.3.2 Handling of specimens by pathologists
Specimen handling should follow the general rules as published by a collaborative group of pathologists and urologists (6,7). It must be stressed that it may be very difficult to confirm the presence of a neoplastic lesion using gross examination of the cystectomy specimen after TUR or chemotherapy, so the entire retracted or ulcerated area must be included.

It is mandatory to study the urethra, ureter, and prostate in men and the radial margins (8). In urethra-sparing cystectomy, the level of urethral dissection, the completeness of the prostate specifically at the apex (in men), and the inclusion of the entire bladder neck and amount of adjacent urethra (in women) should be documented. All lymph node specimens should be provided in their totality, in clearly labeled containers. In case of doubt, or if there is adipose differentiation of the lymph node, the entire specimen is to be included.

Lymph nodes should be counted and measured on slides, and capsular bursting and the percentage of lymph-node invasion should be reported, as well as vascular emboli. If there is metastatic spread into the perivesical fat without real lymph node structures (capsule, subcapsular sinus), this localisation should nevertheless be considered as N+.

Fresh frozen sections can be helpful in determining the treatment strategy. A recent study confirmed the reliability of fresh frozen sections of obturator lymph nodes, but similar studies are warranted to confirm these results (9). As yet, fresh frozen sections have mainly been used in the setting of clinical studies.

3.3.3 Pathology of muscle-invasive bladder cancer
In muscle-invasive bladder cancer, there are usually no cases of PUNLMP or low-grade carcinoma. All cases are high-grade urothelial carcinomas. For this reason, no further prognostic information can be provided by grading the lesions (10). However, some morphological subtypes can be helpful in assessing the prognosis and treatment options. The following differentiation is currently used:

1. Urothelial carcinoma (more than 90% of all cases).
2. Urothelial carcinomas with squamous and/or glandular partial differentiation (11,12).
3. Micropapillary urothelial carcinoma.
4. Nested carcinoma (13).
5. Urothelial carcinomas with trophoblastic differentiation.
7. Spindle cell carcinomas.

For staging, TNM 2002/2010 (6th or 7th edition) is recommended (both editions are identical for bladder cancer). Blood vessel invasion and lymph node infiltration have an independent prognostic significance (15). It
appears that the pN category is closely related to the number of lymph nodes studied by the pathologist (16). For this reason, some authors have reported that more than nine lymph nodes have to be investigated in order to reflect pN0 appropriately (17).

3.3.4 **pT2 substaging in node-negative disease after cystectomy**

In 1997, the American Joint Committee on Cancer (AJCC) updated the TNM staging system and introduced substaging for the T2 tumour stage (18). The latest version was published in 2009, but without any changes from the previous 2002 version (1). This substratification was intended to provide better risk assessment for follow-up strategies and to improve counselling of patients for adjuvant treatment options (19). However, in patients with node-negative, pT2a-T2b bladder cancer, subsequent studies have challenged the prognostic importance of substratifying pT2 tumours into those involving the inner half of the detrusor muscle (T2a) or its outer half (T2b) and have suggested that the two substages should be consolidated into one (20-22). The limitations of these studies were that the extent of lymphadenectomy and the numbers of retrieved lymph nodes were not exactly reported, which may have biased the final survival analysis (22). In addition, patients with non-urothelial cell carcinoma and those who underwent neoadjuvant chemotherapy were not excluded from the analyses (20,21).

A recent multicentre series including 565 patients with pT2 urothelial carcinoma of the bladder therefore attempted to overcome these limitations and reported significant differences in survival between the two substages in node-negative pT2 disease (23). These findings have also been confirmed in a single-centre Egyptian cohort including 1,737 patients with pT2 bladder cancer, 54% of whom had squamous cell carcinomas (24). Furthermore, significant differences in the recurrence-free and cancer-specific survival have also been confirmed in a single-centre series of patients with pT2 urothelial carcinoma of the bladder who were treated with an extended pelvic lymphadenectomy approach (25). pT2 substaging has also recently been incorporated into prognostic models designed to predict upstaging and recurrence after radical cystectomy. A multicentre study has suggested using a weighted prognostic model for patients with node-negative pT2 bladder cancer. Among various independent risk factors (presence of high-grade disease or lymphovascular invasion), pT2 substaging was the strongest one for recurrence-free survival (26). This finding was also confirmed in a large single-centre series including 948 patients with cT2N0M0 bladder carcinoma, in which pT2 substaging was also found to be predictive of the risk of recurrence (27,28). In conclusion, the present data support the current approach using substratification of node-negative pT2 bladder cancer and can be used to tailor the need for adjuvant treatment.

New prognostic markers are under investigation (29). Currently, there is insufficient evidence to recommend the standard use of the prognostic marker p53 in high-risk muscle-invasive disease, as it does not yield sufficient data on which to base treatment in an individual patient.

4. DIAGNOSIS AND STAGING

4.1 Primary diagnosis

4.1.1 Symptoms

Painless haematuria is the most common presenting complaint. Others include urgency, dysuria, increased frequency and, in more advanced tumours, pelvic pain and symptoms related to urinary tract obstruction.

4.1.2 Physical examination

Physical examination should include rectal and vaginal bimanual palpation. A palpable pelvic mass can be found in patients with locally advanced tumours. In addition, bimanual examination under anaesthesia should be carried out before and after TUR to assess whether there is a palpable mass or if the tumour is fixed to the pelvic wall (1,2). However, considering the discrepancy between bimanual examination and pT stage after cystectomy (11% clinical overstaging and 31% clinical understaging) some caution is suggested with the interpretation of bimanual examination (3).
4.1.3 **Bladder imaging**

Patients with a bladder mass identified by any diagnostic imaging technique should undergo cystoscopy, biopsy and or resection for histopathological diagnosis and staging.

4.1.4 **Urinary cytology and urinary markers**

Examination of a voided urine or bladder-washings for exfoliated cancer cells has high sensitivity in high-grade tumours (LE: 3) and is useful indicator in cases of high-grade malignancy or CIS.

Positive urinary cytology may originate from a urothelial tumour located anywhere in the urinary tract. Evaluation of cytology specimens can be hampered by low cellular yield, UTIs, stones or intravesical instillations, but for experienced readers, specificity exceeds 90% (4,5) (LE: 2b). However, negative cytology does not exclude tumour. Cytology should be performed on fresh urine with adequate fixation. Early morning urine is not suitable as cytolysis may often be present. There is no known urinary marker specific for the diagnosis of invasive bladder cancer (6).

4.1.5 **Cystoscopy**

Ultimately, the diagnosis of bladder cancer is made by cystoscopy and histological evaluation of resected tissue. In general, cystoscopy is initially performed in the office using flexible instruments. If a bladder tumour has been visualised unequivocally in earlier imaging studies, such as computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound (US), a diagnostic cystoscopy may be omitted and the patient can proceed directly to TUR for a histological diagnosis.

A careful description of the cystoscopic findings is necessary. This should include documentation of the site, size, number, and appearance (papillary or solid) of the tumours, as well as a description of mucosal abnormalities. Use of a bladder diagram is recommended.

The use of photodynamic diagnosis could be considered, especially if a T1 high-grade tumour is present, to find associated CIS. The additional presence of CIS may lead to a modified treatment plan (see also Section 5.1). Photodynamic diagnosis is highly sensitive for the detection of CIS; with experience, the rate of false-positives may be similar to the technique of regular white light cystoscopy (7).

4.1.6 **Transurethral resection (TUR) of invasive bladder tumours**

The goal of TUR is to enable histopathological diagnosis and staging, which requires the inclusion of bladder muscle in the resection biopsies.

The strategy of resection depends on the size of the lesion. Small tumours (less than 1 cm) can be resected en bloc, where the specimen contains the complete tumour plus a part of the underlying bladder wall including bladder muscle. Larger tumours have to be resected separately in fractions, which include the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle and the edges of the resection area. At least the deepest part of the resection specimen must be referred to the pathologist in a separate labelled container to enable him to make a correct diagnosis. Avoid cauterisation as much as possible during resection to prevent tissue destruction. In cases in which photodynamic diagnosis is used, fluorescing areas should be biopsied in order to detect primary or associated CIS lesions. Fluorescence endoscopy should not be used in the first 6 weeks after any instillation therapy due to a higher rate of false-positive results.

4.1.7 **Random bladder and prostatic urethral biopsy**

Bladder tumours are often multifocal and can be accompanied by CIS or dysplasia. These lesions may present themselves as velvet-like, reddish areas, indistinguishable from inflammation, or may not be visible at all.

The biopsies from normal-looking mucosa in patients with invasive bladder tumours, so-called random biopsies (R-biopsies) show a low yield (8). Fluorescence cystoscopy is performed using filtered blue light after intravesical instillation of a photosensitiser, which was experimentally 5-aminolevulinic acid (5-ALA), and more recently hexaminolaevulinate (HAL), following approval by the European Medicines Agency. It has been confirmed that fluorescence-guided biopsy and resection are more sensitive than conventional procedures in detecting malignant tumours, particularly CIS (9-12) (LE: 2a). However, false-positive results may be induced by inflammation, recent TUR or intravesical instillation therapy. A recent multicentre, prospective, international trial showed that, in experienced hands, the rate of false-positives is not higher than seen in regular, white-light cystoscopy (7). Material obtained by random or directed biopsies must be sent for pathological assessment in separate containers.

The involvement of the prostatic urethra and ducts in male patients with bladder tumours is reported. The exact risk is not known, but it seems to be higher if the tumour is located on the trigone or bladder neck, in the
presence of bladder CIS and in multiple tumours (13,14) (LE: 3). Identification of involvement of the prostatic urethra can be determined either at the time of primary TUR or by frozen section during the cystoprostatectomy procedure. A frozen section has a higher negative predictive value and is more accurate (15-17).

4.1.8 Second resection
There is a significant risk of leaving residual tumour in the bladder after the initial TUR (18,19) (LE: 1). Residual disease is observed in 33-53% of patients (19-25). The tumour may be understaged by the initial resection. There is a 4-25% probability that tumours initially staged as non-muscle invasive are muscle-invasive (20,21). Correct staging is extremely important since it will directly affect the type of treatment. A second TUR should always be performed if the initial resection has been incomplete, e.g. when multiple and/or large tumours are present, or if the pathologist reports that the specimen contains no muscle tissue. A second TUR should be performed when a high-grade, non-muscle-invasive tumour or a T1 tumour is detected at the initial TUR. There is no consensus about the strategy and timing of a second TUR. Most authors recommend resection at 2-6 weeks after the initial TUR. The procedure should include a resection of the primary tumour site.

4.1.9 Concomitant prostate cancer
Ruling out prostate cancer is important since 25-46% of patients undergoing cystectomy for bladder cancer (26,27) have prostate cancer confirmed by histopathology analysis of the resected specimen.

4.2 Imaging for staging MIBC
The treatment and prognosis for MIBC is determined by tumour stage and grade (29). In clinical practice, CT and MRI are the imaging techniques used. The purpose of using imaging for staging MIBC is to determine prognosis and provide information to assist with treatment selection. Tumour staging must be accurate to ensure the correct choice of treatment is made. Imaging parameters required for staging MIBC are:
- the extent of local tumour invasion;
- tumour spread to lymph nodes;
- tumour spread to the upper urinary tract and other distant organs (liver, lungs, bones, peritoneum, pleura, adrenal glands and others).

4.2.1 Local staging of MIBC
Both CT and MRI may be used for assessment of local invasion, but they are unable to diagnose accurately microscopic invasion of perivesical fat (T3a) (30). The principal aim of CT and MRI is therefore to detect T3b disease or higher.

4.2.1.1 MRI for local staging of invasive bladder cancer
Magnetic resonance imaging has superior soft tissue contrast resolution compared with CT, but poorer spatial resolution. In studies performed before the availability of multidetector CT, MRI was reported as more accurate in local assessment. The accuracy of MRI for primary tumour staging varies from 73% to 96% (mean 85%). These values were 10-33% (mean 19%) higher than those obtained with CT (31). Dynamic contrast-enhanced MRI may help to differentiate bladder tumour from surrounding tissues or post-biopsy reaction, because
enhancement of the tumour occurs earlier than the normal bladder wall due to neovascularisation (32-34).

In 2006, a link was established between the use of gadolinium-based contrast agents and nephrogenic systemic fibrosis (NSF), which may result in a fatal or severely debilitating systemic fibrosis. Patients with impaired renal function are at risk of developing NSF and the non-ionic linear gadolinium-based contrast agents should be avoided (gadodiamide, gadopentetate dimeglumine and gadoversetamide). A stable macrocyclic contrast agent should be used (gadobutrol, gadoterate meglumine or gadoteridol). Alternatively, contrast-enhanced CT could be performed using iodinated contrast media (35) (LE: 4).

4.2.1.2 CT imaging for local staging of MIBC
The advantages of CT include high spatial resolution, shorter acquisition time, wider coverage in a single breath hold and lower susceptibility to variable patient factors. Computed tomography is unable to differentiate between stages Ta to T3a, but it is useful for detecting invasion into the perivesical fat (T3b) and adjacent organs. The accuracy of CT in determining extravesical tumour extension varies from 55% to 92% (36) and increases with more advanced disease (37).

4.2.2 Imaging of lymph nodes in MIBC
The assessment of metastases to lymph nodes based simply on size is limited by the inability of both CT and MRI to identify metastases in normal-sized or minimally enlarged nodes. The sensitivity for detection of lymph node metastases is low, ranging from 48-87%. Specificity is also low as nodal enlargement may be due to benign disease. Overall, CT and MRI show similar results in the detection of lymph node metastases in a variety of primary pelvic tumours (38-43). Pelvic nodes, measured on CT or MRI, greater than 8 mm and abdominal nodes greater than 10 mm in a maximum short-axis diameter, should be regarded as pathologically enlarged. (44,45).

Currently, there is no evidence supporting the routine use of positron emission tomography (PET), computed tomography (PET/CT) in the nodal staging of bladder cancer, although the method has been evaluated with varying results in small prospective trials (46-49).

4.2.3 Upper urinary tract urothelial carcinoma (UTUC)
Excretory-phase computed tomography urography is the imaging technique with the highest diagnostic accuracy for UTUC and has replaced conventional intravenous urography and ultrasonography as the first-line imaging test for investigating high-risk patients (50). The sensitivity of CT urography for UTUC is reported to range from 0.67 to 1.0 and specificity from 0.93 to 0.99 depending on the technique used (51-58). Attention to technique is therefore very important for optimum results.

For UTUC detected by CT urography, a biopsy for histopathological confirmation of diagnosis is recommended to eliminate false-positive results and to provide information regarding the grade of the tumour to aid in the choice of treatment. (52,53,59-61). This is usually performed ureteroscopically.

4.2.4 Distant metastases other than lymph nodes
Prior to any treatment aimed at cure, it is essential to evaluate the presence of distant metastases. Computed tomography and MRI are the diagnostic techniques of choice to detect metastases to lung and liver. Metastases to bones or brain at the presentation of invasive bladder cancer are rare. A bone scan and additional brain imaging are therefore not routinely indicated unless the patient has specific symptoms or signs to suggest bone or brain metastases (62,63). Magnetic resonance imaging is more sensitive and specific for diagnosing bone metastases than bone scintigraphy (64,65) (LE: 2b).

4.2.5 Future developments
Evidence is accruing in the literature suggesting that FDG-PET/CT might have potential clinical use for staging metastatic bladder cancer (66,67) but there is no consensus as yet. The results of further trials are awaited before a recommendation can be made.

Recently, the first study was published showing the feasibility of diffusion-weighted imaging (DWI) over T2W and DCE for assessing the therapeutic response to induction chemotherapy against MIBC (68). The high specificity of DWI indicates that DWI is useful for accurate prediction of a complete histopathological response, allowing better patient selection for bladder-sparing protocols. Results from prospective studies are awaited.

5. TREATMENT FAILURE OF NON-MUSCLE INVASIVE BLADDER CANCER

5.1 High-risk non-muscle-invasive urothelial carcinoma

The recurrence and progression rate of NMIBC is strongly associated with tumour grade and invasion into the lamina propria. The progression to T2 tumours varies from 6% to 25% in Ta and from 27% to 48% in T1 tumours of all grades. Inter- and intra-observer varying abilities in grading and staging and the completeness of TUR are key variables that confound the results of present long-term studies of TUR, with or without intravesical therapy.

The understaging error in TaT1 tumours of 35-62% presented in large cystectomy series is due to the presence of recurrent tumours of largely unknown pre-cystectomy therapy and the lack of a second TUR (1-3) (LE: 3). The latter identifies 24-49% of T2 tumours that have been diagnosed initially as non-muscle-invasive tumours (4,5) (LE: 3). However, in spite of these disadvantages, recent meta-analyses have demonstrated that Bacillus Calmette-Guérin (BCG) therapy prevents the risk of tumour recurrence (6,7). Two other meta-analyses showed that BCG therapy decreases the risk of tumour progression (8,9).

So far, no significant overall- or disease-specific survival advantages have been shown, as compared to no intravesical therapy (8-10) (LE: 1).

The disease progression rate is low in patients with small tumours (< 3 cm) and without associated CIS. Twenty per cent of patients progress within 5 years, with approximately 90% of patients keeping their intact bladder during follow-up of up to 10 years (11) (LE: 2). However, in a recently published, prospective, multicentre trial, the progression rate was significantly lower than previously reported, even when the presence of concomitant CIS was considered. This was probably due to the combination of a second resection, prior to inclusion in the trial and maintenance treatment as part of the protocol (12) (LE: 1b).

Progression to MIBC significantly decreases cancer-specific survival (CSS). In a review of 19 trials and 3,088 patients, CSS after progression from NMIBC to MIBC was 35%, which is significantly worse compared to patients with MIBC without a history of NMIBC. This underlines the need to recommend early radical treatment in case of intravesical therapy failure (13,14).
According to the EAU NMIBC Guidelines, it is reasonable to propose immediate radical cystectomy to those patients with non-muscle-invasive tumour who are at highest risk of progression (14). These are:

- multiple and/or large (> 3 cm) T1, high-grade (G3) tumours;
- T1, high-grade (G3) tumours with concurrent CIS;
- recurrent T1, high-grade (G3) tumours;
- T1G3 and CIS in prostatic urethra;
- micropapillary variant of urothelial carcinoma.

Although the percentage of patients with primary TaT1 tumours and the indication for cystectomy in TaT1 tumours is not specified in large cystectomy series, the 10-year recurrence-free survival is approximately 80% and similar to TUR and BCG maintenance therapy (1,3,15,16) (LE: 3). In the case of recurrent TaT1, mostly associated with CIS, the understaging at the time of cystectomy is 34%, but the 10-year survival is not significantly different for patients with pT1 and pT2 tumours (17) (LE: 3). This is in contrast to an earlier report, which indicates a significantly worse outcome for patients with previous TUR(s) (18) (LE: 3).

Undoubtedly, patients with muscle-invasive recurrence are best treated with radical cystectomy. However, the outcome in terms of the presence of lymph node metastases and cancer-free survival may be inferior to patients with the same tumour stage, but who receive radical cystectomy at first presentation (19) (LE: 3).

There is uncertainty about the treatment of patients who develop tumour recurrence in spite of BCG therapy because of different BCG therapy schedules and the absence of a uniform definition of BCG failure. It has been indicated that the recurrence (persistence) of tumour at 9 months in spite of BCG therapy is associated with a 30% chance of invasive tumours and death due to metastatic disease (20) (LE: 3). Solsosa et al. demonstrated that 80% of patients who had persistent disease at 3 months progressed to muscle-invasive disease (21) (LE: 3). In addition, adequate tissue sampling from the prostatic urethra is an essential factor in considering the outcome of conservative treatment, since urethral tumours are associated with a significant decrease in tumour-free survival (22) (LE: 3). However, with careful selection and surveillance, a durable complete response can also be achieved in patients diagnosed with superficial bladder transitional cell carcinoma involving the prostatic urethra (23). Based on these findings, cystectomy should be performed in appropriate patients at least at 9 months, because additional BCG therapy yields a response rate of only 27-51% and of unknown duration (24,25) (GR: C). Salvage chemotherapy is associated with a limited response and should not be offered (26,27) (LE: 3).

Patients with disease recurring within 2 years of initial TUR plus BCG therapy have a better outcome than patients who already have muscle-invasive disease, indicating that cystectomy should be performed at first recurrence, even in non-muscle-invasive disease (19) (LE: 3; GR: C).

### 5.2 Carcinoma in situ

Primary CIS confined to the bladder is treated with intravesical BCG, yielding a complete response rate of 83-93% (28,29) (LE: 2). Carcinoma in situ associated with TaT1 is treated according to the overt tumour.

Approximately 50% of patients develop recurrent disease with muscle invasion or extravesical tumour (28,30) (LE: 2). Between 11% and 21% die of the disease within 5-7 years after an initial complete response (28,31) (LE: 2). Non-responders or incomplete responders have a significant risk of tumour progression of 33-67% (21,32) (LE: 2).

The current guidelines on non-muscle-invasive bladder cancer define BCG failure as:

- a. Whenever muscle-invasive tumour is detected during follow-up.
- b. If high-grade, non-muscle-invasive tumour is present at both 3 and 6 months.
- c. High-grade recurrence after BCG (more recurrences, Ta → T1 or upgrading, appearance of CIS).

In patients with tumour present at 3 months, an additional BCG course can achieve a complete response in > 50% of cases, both in patients with papillary tumours and CIS but with increasing risk of progression.

There are now several bladder preservation strategies available that can be categorised as immunotherapy, chemotherapy, device-assisted therapy, and combination therapy (33). However, experience is limited and treatments other than radical cystectomy must be considered oncologically inferior at the present time (34-36).

6. NEOADJUVANT CHEMOTHERAPY

6.1 Introduction
The standard treatment for patients with muscle-invasive bladder cancer is radical cystectomy. However, this ‘gold standard’ only provides 5-year survival in about 50% of patients (1-5). In order to improve these unsatisfactory results, the use of peri-operative chemotherapy has been explored since the 1980s. There are many advantages of administering chemotherapy before planned definitive surgery (or radiation therapy) to patients with operable urothelial carcinoma of the urinary bladder, muscle-invasive, clinically negative nodes (cN0), including:

- Chemotherapy is delivered at the earliest time-point, when the burden of micrometastatic disease is expected to be low.
- Potential reflection of in-vivo chemosensitivity.
- Tolerability of chemotherapy is expected to be better before cystectomy rather than after.
- Hypothetically patients with micrometastatic disease might respond to neoadjuvant therapy and reveal a favourable pathological status, determined mainly by negative lymph node status and negative surgical margins.

6.2 The role of imaging to assess treatment response
For patients who respond to neoadjuvant chemotherapy, known as responders, and especially those who show a complete response (pT0 N0), neoadjuvant chemotherapy has a major impact on overall survival (OS) (6). The overtreatment of non-responders and patients in the non-target population (i.e. patients without micrometastatic disease) are major drawbacks of neoadjuvant chemotherapy. The best option is early pre-operative identification of responders utilizing tumour molecular profiling in TUR-specimens, but there is still a lack of reliable methods for clinical use (7). Alternatively, some investigators are exploring imaging methods for the early identification of responders at the time of treatment cycles.

A small pilot study, using PET imaging to monitor response to chemotherapy, suggested that alterations in tumour metabolism occur long before visible changes appear on CT or MRI (8). In a recent retrospective evaluation of 27 patients undergoing total or partial cystectomy after neoadjuvant chemotherapy (n = 8), neoadjuvant chemoradiation (n = 10), or no neoadjuvant therapy (n = 9), tumour stage assessed by MRI was only consistent with post-cystectomy pathology findings in 59.3 % of the patients (9).

Another study evaluated conventional vs. fast dynamic contrast-enhanced MRI before and after 2, 4 and 6 cycles of MVAC (10). Only 9 of 22 patients subsequently underwent cystectomy. After two MVAC cycles, the
accuracy, sensitivity, and specificity of conventional MRI in distinguishing responders from non-responders were 73%, 79%, and 63%, respectively. With the dynamic technique, these figures were 95%, 93%, and 100%, respectively. The differences were not significant. The authors concluded that after two cycles, dynamic MRI helped detect 13 of 14 responders and eight of eight non-responders.

Finally, the application of results from the imaging of treatment responses in the adjuvant (metastatic) setting to the neoadjuvant setting should be done with caution. Finding robust and reproducible methods of imaging, early in the selection process for neoadjuvant chemotherapy, remains challenging.

In the adjuvant setting, present metastatic marker lesions are evaluated that allow testing of different and new imaging response criteria (11), while in the neoadjuvant setting the only marker lesion is the primary tumour itself. Tumour size measurement prior to and during neoadjuvant chemotherapy should be done to identify responders and non-responders.

Attempts have been made in small published series to identify responders while monitoring patients undergoing neoadjuvant chemotherapy, suggesting that the response after two cycles of neoadjuvant chemotherapy is related to outcome, but firm conclusions cannot yet be made (8,9).

The meaning of stable disease after two cycles of neoadjuvant chemotherapy is unknown. To identify progression during neoadjuvant chemotherapy imaging is being used, notwithstanding the lack of published data to support its efficacy.

</tbody>
</table>

**Recommendations**

In case of progression under neoadjuvant chemotherapy, this treatment should be discontinued.

### 6.3 Disadvantages of neoadjuvant chemotherapy

The disadvantages of neoadjuvant chemotherapy are:

- Clinical staging using CT or MR imaging may often result in over- and understaging and has a staging accuracy of only 70% (12,13). Overtreatment is the possible negative consequence.

- Delayed cystectomy might compromise the outcome in patients not sensitive to chemotherapy (14,15).

The side effects of neoadjuvant chemotherapy affecting the outcome of surgical morbidity need to be considered. In one randomised trial (16), the same distribution of post-operative complications grade 3-4 was seen in both trial arms (16). In the combined Nordic trials NCS1 + NCS2, (n = 620), neoadjuvant chemotherapy did not have any major adverse effect on the percentage of performable cystectomies. In the intention-to-treat analysis, the cystectomy-frequency was 86% in the experimental arm and 87% in the control arm, while 71% of patients received all three chemotherapy cycles (17).

Several randomised phase III trials investigated the question of whether or not neoadjuvant chemotherapy improved survival, with conflicting results (18-34).

Differences in trial design were mainly the type of chemotherapy (i.e. single-agent cisplatin or combination chemotherapy) and the number of cycles planned. From the statistical point of view, the studies differed in size, patient characteristics (e.g. clinical T-stages included) and the type of definitive treatment allowed (cystectomy and/or radiotherapy). Patients had to be fit for cisplatin. Because of the lack of clarity, even though a considerable number of randomised trials had been performed, three meta-analyses were undertaken to answer the very important question of whether or not neoadjuvant chemotherapy prolongs survival (35-37).

- The first meta-analysis, published in 2003 (35), included 10 randomised trials (except for results of the INT 0080-study [26]) and showed a 13% reduction in the risk of death, equivalent to 5% absolute benefit at 5 years (increased overall survival [OS] from 45% to 50%).
The second meta-analysis, published in 2004 (36), included 11 of 16 randomised trials with OS data of 2605 patients. A statistically significant decrease in the risk of death (10%) was seen, corresponding to an absolute improvement in OS of 5% (from 50% to 55%).

In the most recent meta-analysis, published in 2005 (38), with updated independent patient data of 11 randomised trials (3005 patients), a statistically significant survival benefit in favour of neoadjuvant chemotherapy was also seen. The results of this analysis confirmed the previously published data and showed 5% absolute improvement in survival at 5 years. The Nordic combined trial showed an absolute benefit of 8% in survival at 5 years and 11% in the clinical T3 subgroup, translating into nine patients needed to treat (17). Of note, only cisplatin combination chemotherapy with at least one additional chemotherapeutic agent resulted in a meaningful benefit (35,37); the regimens tested were MVA(E)C, CMV, CM, cisplatin/adriamycin, cisplatin/5-fluorouracil (5-FU), and CarboMV. To date, it is unknown if more modern chemotherapy regimens are as effective.

The updated analysis of the largest randomised phase III trial (24) with a median follow-up of 8 years confirmed the former results and provided some additional interesting findings:

- A 16% risk reduction of death.
- An improvement in 10-year survival from 30% to 36% with neoadjuvant CMV.
- No benefit for locoregional control and locoregional disease-free survival, with the addition of neoadjuvant CMV independent of the definitive treatment.

The presence of micrometastases is postulated to be lower in smaller tumours (T2) compared to more extensive tumours (T3b-T4b). T4 stage tumours are prone to a higher degree of clinical understaging because macrometastatic nodal deposits are detected more often in post-cystectomy specimens of these extensive tumours (38). Further data support the use of neoadjuvant chemotherapy in the subgroup of T2b-T3b tumours (former classification T3), which has been shown to provide a modest but substantial improvement in long-term survival and significant downstaging.

7. RADICAL SURGERY AND URINARY DIVERSION

7.1 Removal of the tumour-bearing bladder

7.1.1 Background

Radical cystectomy is the standard treatment for localised MIBC in most countries of the Western world (1,2). Recent interest in patients’ quality of life (QoL) has increased the trend toward bladder preservation treatment modalities, like radio- and/or chemotherapy (see Chapters 9 and 10). Performance status and age influence the choice of primary therapy, as well as the type of urinary diversion, with cystectomy being reserved for younger patients without concomitant disease and with a better performance status. The value of assessing overall health before recommending and proceeding with surgery was emphasised in a recent multivariate analysis (3). The analysis found an association between comorbid disease and adverse pathological and survival outcome following radical cystectomy (3). Performance status and comorbidity have a different impact on treatment outcome and must be evaluated independently (4).

Controversy remains about age, radical cystectomy and the type of urinary diversion. Cystectomy is associated with the greatest risk reduction in disease-related and non-disease-related death in patients older than 80 years (3). The largest, retrospective, single-institution study on cystectomy to date found that patients above 80 years had increased post-operative morbidity but not an increased mortality. Although some patients successfully underwent a neobladder procedure, most patients were treated with an ileal conduit diversion (5). It is particularly important to evaluate the function and QoL of elderly patients using a standardised geriatric assessment, as well as carrying out a standard medical evaluation (see Section 7.1.4) (6).

7.1.2 Timing and delay of cystectomy

A retrospective series of 153 patients, with a clear indication for radical surgery of locally advanced bladder cancer, found that patients treated more than 90 days after the primary diagnosis showed a significant increase in extravesical disease (81 vs 52%) (7).

The delay in cystectomy not only affects the outcome of treatment, but also the type of urinary diversion. In organ-confined urothelial cancer of the bladder, the average time from primary diagnosis to cystectomy was 12.2 months in patients who received a neobladder and 19.1 months in those who received an ileal conduit. This was even more noticeable with organ-confined invasive cancer; the average time to surgery was 3.1 months with a neobladder and 15.1 months with an ileal conduit (8). Similar results have been observed in a series of 247 patients: recurrence-free survival and OS were significantly better in patients treated before 90 days compared to others treated after 90 days (9).

7.1.3 Indications

Traditionally, radical cystectomy was recommended for patients with MIBC T2-T4a, N0-Nx, M0 (1). Other indications include high-risk and recurrent superficial tumours, BCG-resistant Tis, T1G3 (see Chapter 5), as well as extensive papillary disease that cannot be controlled with TUR and intravesical therapy alone.

Salvage cystectomy is indicated for non-responders to conservative therapy, recurrences after bladder-sparing treatments, non-urothelial carcinomas (these tumours respond poorly to chemo- and radiotherapy), and as a purely palliative intervention, including in fistula formation, pain or recurrent macrohaematuria (see Section 8.1 Palliative cystectomy).

7.1.4 MIBC and comorbidity

Complications related to radical cystectomy may be directly related to pre-existing patient comorbidities as well as the surgical procedure, the bowel anastomosis, or the urinary diversion. A significant body of literature...
has evaluated the usefulness of age as a prognostic factor for radical cystectomy (10-12). Advanced age has been identified as a risk factor for complications due to radical cystectomy, although chronological age is less important than biological age. Other risk factors for morbidity include prior abdominal surgery, extravesical disease, and prior radiotherapy (13), while an increased body mass index is associated with a higher rate of wound dehiscence and hernia (14).

7.1.4.1 Evaluation of comorbidity
Rochon et al. showed that an evaluation of comorbidity provides a better indicator of life expectancy in MIBC than does the patient’s age (15). The evaluation helps to identify the medical conditions likely to interfere with, or have an impact on, treatment and the evolution and prognosis of MIBC (16).

The value of assessing overall health before recommending and proceeding with surgery was emphasised by Zietman et al., who demonstrated an association between comorbidity and adverse pathological and survival outcome following radical cystectomy (17). Similar results were found for the impact of comorbidities on cancer-specific and other-cause mortalities in a population-based competing risk analysis of more than 11,260 patients from the SEER registries. Age carried the highest risk for other-cause mortality but not for increased cancer-specific death, while the stage of locally advanced tumour was the strongest predictor for decreased cancer-specific survival (18). Stratifying elderly patients according to their risk-benefit profile using a multidisciplinary approach will help to select patients most likely to benefit from radical surgery and to optimise treatment outcomes (19).

Unfortunately, most series evaluating radical cystectomy do not include indices of comorbidity in the patient evaluation.

7.1.4.2 Comorbidity scales
A range of comorbidity scales have been developed (20), six of which have been validated (LE: 3):

- CIRS (Cumulative Illness Rating Scale) (21);
- Kaplan-Feinstein index (22);
- Charlson Comorbidity Index (CCI) (23);
- ICD (Index of Coexistent Disease) (24);
- ACE-27 (25);
- Total Illness Burden Index (TIBI) (26).

The Charlson Comorbidity Index ranges from 0 to 30 according to the importance of comorbidities described in four levels and is calculated by the healthcare practitioner from the patient’s medical record. The score was widely studied in patients with bladder cancer and found to be an independent prognostic factor for perioperative mortality (27,28), overall mortality (29), and cancer-specific mortality (30-33). Only the age-adjusted version of the Charlson comorbidity index was correlated with both cancer-specific mortality and other cause-mortality (34).

The ICD evaluates 14 possible comorbidities and is also calculated from the patient’s medical record.

The CIRS provides a quantification of the severity of organic disease in 14 systems and is calculated from the medical record. Nurses and doctors were shown to provide comparable calculations of CIRS (35). Although CIRS has been validated in elderly subjects (36,37), it has not been validated in bladder cancer treatment.

The Kaplan Feinstein index evaluated 12 comorbidities using a score from 0 to 3, with 0 indicating no problem, 1 indicating a light and non-chronic decompensated comorbidity, 2 indicating a significant decompensation, and 3 indicating severe decompensation. The final score of 0-3 is the highest rating given to a disease. The final score may be 3 if two or more pathologies have been given a score of 2. The healthcare practitioner calculates the Kaplan Feinstein index data from the medical record.

The TIBI evaluates the 16 diseases across 110 items. The TIBI questionnaire is completed by the patient himself. The TIBI was initially validated in a cohort of patients with type 2 diabetes. The TIBI was then correlated to the QoL, age, number of days spent in bed during the previous three months, and reduced mobility in a cohort of 1,638 men with a prostate cancer (38). None of the four last scales mentioned above (ICD, CIRS, Kaplan Feinstein index, TIBI) were not validated in the setting of bladder cancer treatments.

Performances of the Charlson Comorbidity Index and ACE-27 are approximately equivalent (LE: 3). The age-adjusted Charlson Comorbidity Index (Table 4) is the most widely used comorbidity index in cancer for estimating long-term survival and must be easily calculated using a specific calculator (39).
Table 4: Calculation of Charlson Comorbidity Index

Interpretation
1. Calculate Charlson Score or Index = i
   a. Add comorbidity score to age score
   b. Total denoted as ‘i’ in the Charlson Probability calculation (see below). i = sum of comorbidity score to age score.

2. Calculate Charlson Probability (10-year mortality)
   a. Calculate $Y = 10 \times 0.9$
   b. Calculate $Z = 0.983^Y$ (where Z is the 10-year survival)

The assessment of the health of the oncology patient must be supplemented by measuring the activity level of the patient. Extermann et al. showed that there was no correlation between morbidity and competitive activity level of the patient (4). ECOG-PS scores and Karnofsky index have been validated to measure the activity level of the patient (LE: 3) (40). Performance status was correlated to patient overall survival after radical cystectomy (32,41) and palliative chemotherapies (42-44).

The ASA score has been validated to assess, prior to surgery, the risk of post-operative complications. In the bladder cancer setting, ASA scores equal to or greater than 3 were associated with major complications (45,46), particularly those related to the type of urinary diversion (Table 5) (47).

Table 5: ASA score (48).

According to a consensus conference of the National Institutes of Health, the aim of the Standardized Geriatric Assessment (SGA) is to discover, describe and explain the many problems of the elderly, to catalogue the resources and strengths of the elderly, to assess needs services to the individual and to develop a coordinated plan of care. The SGA is thus a medico-psycho-social index.

The SGA can be carried out by means of several protocols. These protocols differ in the completeness of diagnostic research. The protocol is the most complete Comprehensive Geriatric Assessment (CGA) (49). The CGA is suited to the care of cancer patients (50). In bladder cancer, the CGA was used to adapt gemcitabine chemotherapy in previously untreated elderly patients with advanced bladder carcinoma (51).

The Senior Adult Oncology Program proposed by Balducci et al. presents a less comprehensive evaluation than a SGA evaluation (52). Even though these protocols identified previously unrecognised geriatric medical and social problems, their usefulness is not clearly demonstrated yet. (53). Similarly, the CGA, when performed in patients in general medicine, does not alter the risk of hospitalisation or death within 2 years of the evaluation (54). To provide benefit to patients, the CGA should be associated with the management problems it identifies (55).

### 7.1.5 References

Radical cystectomy - technique and extent

Radical cystectomy also includes the dissection of regional lymph nodes. There is substantial data on the extent of lymphadenectomy. Controversies in evaluating the clinical significance of lymphadenectomy are related to two main aspects of nodal dissection: therapeutic procedure and/or staging instrument.

In the only autopsy investigation performed so far, it was shown that in 215 patients with MIBC and nodal dissemination, the frequency of metastasis was 92% in regional (perivesical or pelvic), 72% in retroperitoneal, and 35% in abdominal lymph nodes. There was also a significant correlation between nodal metastases and concomitant distant metastases (p < 0.0001). Approximately 47% of the patients had both nodal metastases and distant dissemination and only 12% of the patients had nodal dissemination as the sole metastatic manifestation (1).

Several localisation studies of lymphadenectomy (2–7) have demonstrated both retrospectively and prospectively that metastatic lymph nodes in bladder cancer patients are not found outside the pelvis if the pelvic lymph nodes are free of tumour.

An attempt has been made to categorise the extent of lymphadenectomy. A standard lymphadenectomy in bladder cancer patients involves the removal of all nodal tissue cranially up to, and including, the common iliac bifurcation, with the ureter being the medial border, and including the internal iliac, presacral, obturator fossa and external iliac nodes (8). An extended lymphadenectomy includes all lymph nodes in the region of the aortic bifurcation and common iliac vessels medially to the crossing ureters. The lateral boarders are the genitofemoral nerves, caudally the circumflex iliac vein, the ligamentum lacunare and the lymph node of Cloquet, as well as the area described in the standard lymphadenectomy (9–11). A superextended lymphadenectomy extends cephalad to the level of the inferior mesenteric artery (12).

In order to assess how and if cancer outcomes are influenced by the different extents of lymphadenectomy for patients with clinical N0M0 MIBC, a systematic review of the literature was undertaken for comparative studies. The systematic review methodology is outlined in detail elsewhere (13). In brief, a systematic review of the literature was conducted in accordance with the PRISMA guidelines (14). Two independent reviewers
performed abstract and full text screening, data abstraction and risk of bias assessment. The results were tabulated in baseline characteristics and summary of findings tables. A narrative synthesis of the evidence was performed. Out of 1,696 abstracts retrieved and assessed, 18 studies fulfilled the review criteria and were included (15-31,31b). Of the nine studies comparing extended lymphadenectomy with standard or limited lymphadenectomy, six studies reported a survival benefit in favour of extended lymphadenectomy. Two studies compared the results of a high-volume centre performing extended lymphadenectomy vs. another high-volume centre performing a superextended lymph node dissection in patients undergoing radical cystectomy. Both studies reported no difference in regard to overall survival and cancer recurrence.

Two other reviews reported similar findings. Karl et al. (33) concluded that a more limited field of lymph node dissection (LND) in the pelvis was associated with suboptimal staging as well as poorer outcomes compared with a standard or extended lymphadenectomy, both in patients with node-positive and node-negative disease. Svatek and colleagues (34) concluded that extended lymph node dissection (LND) with complete skeletonisation of all pelvic structures up to the mid-upper third of the common iliac vessels was superior to limited LND. However, all of these identified studies suffer from significant methodological limitations and are prone to biases, thereby compromising the quality and reliability of the evidence. Further data from ongoing randomised trials on the therapeutic impact of extent of lymphadenectomy are awaited.

It has been suggested that progression-free survival as well as OS might be correlated with the amount of lymph nodes removed during surgery, although there are no reliable data on the minimum number of lymph nodes which must be removed. Nevertheless, the probability of survival increases with the number of dissected lymph nodes (35). Removal of more than 10-15 lymph nodes has been postulated as sufficient for the evaluation of the lymph node status as well as being beneficial for OS in retrospective studies (7,36,37). The number of lymph nodes removed does, however, not appear to correlate well with the anatomic template of lymphadenectomy. Suggested explanations include variability between patients, difficulties in accurate anatomical assignment of removed lymph nodes, inter-surgeon variability, and differences in method of lymph node submission and processing (38-41).

Laparoscopic/robotic-assisted laparoscopic cystectomy
Laparoscopic cystectomy and robotic-assisted laparoscopic cystectomy (RALC) have been shown to be feasible both in male and female patients (42,43). Both cystectomy and lymphadenectomy have been done in small series, according to the same principles used in cystectomy and anterior exenteration for several decades now (44). However, these techniques are still experimental because of the limited number of cases reported, an absence of long-term oncological and functional outcome data, and a possible selection bias (45,46).

Laparoscopic intracorporeal construction of urinary diversion (with or without robotic assistance) has been tested in small series only (45,47,48). It is a challenging and lengthy procedure with the current technical equipment available and must therefore be regarded as experimental. Laparoscopic cystectomy and pelvic lymphadenectomy (with or without robotic assistance), with extracorporeal construction of urinary diversion, is an option for surgical treatment (LE: 3).

Laparoscopic and robot-assisted radical cystectomy data suffer from selection bias including younger patients, lower stage, and minimal comorbidities compared to most contemporary open series (49-51). This selection bias makes interpretation of peri-operative outcomes difficult.

Urinary diversion after radical cystectomy
From an anatomical standpoint, three alternatives are presently used after cystectomy:
• Abdominal diversion, such as an uretherocutaneousostomy, ileal or colonic conduit, and various forms of a continent pouch.
• Urethral diversion, which includes various forms of gastrointestinal pouches attached to the urethra as a continent, orthotopic urinary diversion (neobladder, orthotopic bladder substitution).
• Rectosigmoid diversions, such as uretero (ileo-) rectostomy.

Different types of segments of the intestinal tract have been used to reconstruct the urinary tract, including the stomach, ileum, colon, and the appendix (52). Several studies have compared certain aspects of health-related QoL, such as sexual function, urinary continence and body image, in patient cohorts with different types of urinary diversion. However, further research is needed on pre-operative tumour stage and functional situation, socioeconomic status, time interval to primary surgery, etc.

Preparations for surgery
For cystectomy, general preparations are necessary as for any other major pelvic and abdominal surgery. If the
urinary diversion is constructed from gastrointestinal segments, the length or size of the respective segments and their pathophysiology when storing urine must be considered (53). Despite the necessary interruption and re-anastomosis of bowel, a formal bowel preparation may not be necessary (54). Furthermore, bowel recovery time has been reduced by the use of early mobilisation, early oralisation and gastrointestinal stimulation with metoclopramide and chewing gum (55).

Patients undergoing continent urinary diversion have to be motivated both to learn about their diversion and to be manually skilful in manipulating their diversion. Contraindications to more complex forms of urinary diversion include:

- debilitating neurological and psychiatric illnesses;
- limited life expectancy;
- impaired liver or renal function;
- transitional cell carcinoma of the urethral margin or other surgical margins.

Relative contraindications specific for an orthotopic neobladder are high-dose pre-operative radiation therapy, complex urethral stricture disease, and severe urethral sphincter-related incontinence (56-58).

7.2.1.1 Patient selection for orthotopic diversion

Radical cystectomy and urinary diversion are the two steps of one operation. However, the literature uniformly reports the complications of radical cystectomy, while ignoring the fact that most complications are diversion-related (59). Age alone is not a criterion for offering continent diversion (60,61). Medical comorbidities, cardiac and pulmonary function and cognitive function are all important factors that should be considered, along with the patient's social support and patient preference.

7.2.2 Ureterocutaneostomy

Ureteral diversion to the abdominal wall is the simplest form of cutaneous diversion. It is considered as a safe procedure. It is therefore preferred in older, or otherwise compromised, patients, who need a supravesical diversion (62,63). However, others have demonstrated that, in carefully selected elderly patients, all other forms of wet and dry urinary diversions, including orthotopic bladder substitutions, are possible (64).

Technically, either one ureter, to which the other shorter one is attached end-to-side, is connected to the skin (transuretero-ureterocutaneostomy) or both ureters are directly anastomosed to the skin. Due to the smaller diameter of the ureters, stoma stenosis has been observed more often than in intestinal stomas (62).

In a recent retrospective comparison with short or median follow-up of 16 months, the diversion-related complication rate was considerably lower for ureterocutaneostomy compared to an ileal or colon conduit (65). Despite the limited comparative data available, however, it has to be taken into consideration that older data and clinical experience suggest stricturing on skin level and ascending UTI are more frequent complications in comparison to an ileal conduit diversion. In a retrospective study comparing various forms of intestinal diversion, ileal conduits had fewer late complications than continent abdominal pouches or orthotopic neobladders (66).

7.2.3 Ileal conduit

The ileal conduit is still an established option with well-known/predictable results. However, up to 48% of patients develop early complications including UTIs, pyelonephritis, uretero-ileal leakage and stenosis (66). The main complications in long-term follow-up studies are stomal complications in up to 24% of cases and functional and/or morphological changes of the upper urinary tract in up to 30% (67-69). An increase in complications was seen with increased follow-up in the Berne series of 131 patients followed for a minimum of 5 years (median follow-up 98 months) (67): the rate of complications increased from 45% at 5 years to 94% in those surviving longer than 15 years. In the latter group, 50% of patients developed upper urinary tract changes and 38% developed urolithiasis.

7.2.4 Continent cutaneous urinary diversion

A low-pressure detubularised ileal reservoir can be used as a continent cutaneous urinary diversion for self-catheterisation; gastric, ileoceleal and sigma pouches have also been described (70-72). Different antireflux techniques can be used (73). Most patients have a well-functioning reservoir with day-time and night-time continence approaching 93% (74). A stomal stenosis in 23.5% of patients with an appendix stoma and 15% with an efferent intussuscepted ileal nipple was observed in a study, reviewing retrospectively the results of more than 800 patients. Stone formation in the pouch occurred in 10% of patients (74-76). In a small series of previously irradiated female patients, incontinence and stomal stenosis was 18% (8/44 patients) (77).
7.2.5  **Ureterocolonic diversion**

The oldest and most common form was primarily a refluxive and later an antirefluxive connection of ureters into the intact rectosigmoidum (uretero [recto] sigmoidostomy) (78,79). Most indications for this procedure have become obsolete due to a high incidence of upper urinary tract infections and the long-term risk of developing colon cancer (80,81). Bowel frequency and urge incontinence were additional side-effects of this type of urinary diversion. However, it may be possible to circumvent the above-mentioned problems by interposing a segment of ileum between ureters and rectum or sigmoid in order to augment capacity and to avoid direct contact between the urothelium and colonic mucosa as well as faeces and urine (82).

7.2.6  **Orthotopic neobladder**

An orthotopic bladder substitution to the urethra is now commonly used both in men and women. Contemporary reports document the safety and long-term reliability of this procedure. In several large centres, this has become the diversion of choice for most patients undergoing cystectomy (58,83,84). In elderly patients (> 80 years), however, it is very rarely performed, even in high-volume expert centres (85,86).

The terminal ileum is the gastrointestinal segment most often used for bladder substitution and there is less experience with ascending colon, including caecum, and the sigmoid (83). The emptying of the reservoir anastomosed to the urethra requires abdominal straining, intestinal peristalsis and sphincter relaxation. Early and late morbidity in up to 22% of the patients is reported (87,88). Long-term complications include diurnal (8-10%) and nocturnal incontinence (20-30%), uroenteric stenosis (3-18%), urinary retention (4-12%) both in males and female patients, metabolic disorders and vitamin B12 deficiency in series with 1054 and more than 1300 patients (58,89). In a recent study, which compared cancer control and the patterns of disease recurrence in neobladder and conduit patients, no cancer-specific survival difference could be identified between the two groups when adjusting for pathological stage (90). Urethral recurrence in neobladder patients seems rare (1.5-7% for both male and female patients) (58,91). These results indicate that the choice of a neobladder both in male and female patients does not compromise the oncological outcome of cystectomy. It remains debatable whether a neobladder is better for QoL compared to a non-continent urinary diversion (92-94).

Various forms of upper tract reflux protection, including a simple isoperistaltic tunnel, an ileal intussusception, a tapered ileal prolongation implanted subserosally, and a direct (sub)mucosal or subserosal ureteral implantation, have been described (76,88). According to the reported long-term results, the upper urinary tract is protected sufficiently by either method.

In conclusion, standard radical cystectomy in male patients with bladder neoplasms includes removal of the entire bladder, prostate, seminal vesicles, distal ureters (length of the segment undefined), and corresponding lymph nodes (extent undefined) (LE: 2b). Currently, it is not possible to recommend a particular type of urinary diversion. However, most institutions will prefer ileal orthotopic neobladders and ileal conduits based on clinical experience (95,96). In selected patients, ureterocutaneostomy is surgically the least burdensome type of diversion (LE: 3). Recommendations related to radical cystectomy and urinary diversions are listed in section 7.6.2.

7.3  **Morbidity and mortality**

In a recent comprehensive long-term study (n = 1054), peri-operative mortality was reported in 3% of cases, and early complications, defined as any complication within 3 months of surgery, in 28% (84,89). Late morbidity is usually due to the type of urinary diversion (see above). Early morbidity associated with radical cystectomy for NMIBC (at high risk for disease progression) is similar and not less than that associated with muscle-invasive tumours (97). In general, a lower morbidity and mortality has been observed by surgeons and by hospitals with a higher case load and therefore more experience (98).

7.4  **Survival**

Research findings have demonstrated good survival outcomes:

- According to a multi-institutional database of 888 consecutive patients undergoing cystectomy and lymphadenectomy for bladder cancer, the outcome at 5 years was 58% for a mean recurrence-free survival and 66% for bladder cancer-specific survival (99).
- The recurrence-free and OS in a large single centre study of 1054 male and female patients was 68% and 66% at 5 years and 80% and 43%, at 10 years, respectively (100).
- In node-positive patients, another study reported that 10-year disease-specific and OS rates were 27.7% and 20.9%, respectively (148). In this cohort, 10-year disease-specific and OS rates were 72.9% vs. 49.1% for organ-confined disease (defined as ≤ pT3a), and 33.3% vs. 22.8% for non-organ-confined disease (101).
- In another study, 5-year recurrence-free survival was 76% in patients with pT1 tumours, 74% for
pT2, 52% in pT3, and 36% in pT4 tumours (102). Tumour stage and nodal involvement are the only independent predictors of survival (103).

8. NON-RESECTABLE TUMOURS

8.1 Palliative cystectomy for muscle-invasive bladder carcinoma

For patients with inoperable locally advanced tumours (T4b, invading the pelvic or abdominal wall), radical cystectomy is not usually a therapeutic option (1). Treatment of these patients remains a clinical challenge. These patients are candidates for palliative treatments, such as palliative radiotherapy.

Inoperable locally advanced tumours may be accompanied by several debilitating symptoms, including bleeding, pain, dysuria and urinary obstruction. There are several treatment options for patients with these symptoms. In advanced bladder cancer complicated by bleeding, cystectomy with urinary diversion is the most invasive treatment. It carries the greatest morbidity and should be considered only if there are no other options (1).

In patients with locally advanced pelvic cancer and urinary bladder involvement, palliative radical cystectomy with urinary diversion using intestinal segments is usually performed for the relief of symptoms such as pain, recurrent bleeding, urgency and fistula formation (2). Zebic, et al. (2005) (3) retrospectively analysed patients aged ≥ 75 years, who had received radical cystectomies with either curative or palliative intent. The indications for palliative cystectomy were advanced pelvic malignancy with severe irritating voiding symptoms, severe pain and recurrent macrohaematuria requiring blood transfusions (3). Zebic, et al. (2005) concluded that elderly people have a greater risk of peri-operative morbidity and mortality, especially those with very advanced pelvic malignancies, who have undergone palliative cystectomy (3).

Advanced MIBC can be associated with ureteral obstruction. In invasive tumours, the mechanism of ureteral obstruction is probably caused by a combination of mechanical blockade by the tumour and invasion of ureteral orifices by tumour cells interfering with ureteral peristalsis. Bilateral ureteral obstruction, or unilateral obstruction to a solitary functioning kidney, can result in uraemia. Treatment of such patients is still a dilemma. El-Tabey et al. retrospectively reviewed the records of patients who presented with bladder cancer and obstructive uraemia (4). Patients with inoperable locally advanced bladder tumours (23 patients, 37.7%) were treated with permanent nephrostomy tubes to relieve obstruction; radical cystectomy was not an option. Ten patients underwent surgery (26.3%); palliative cystectomy without lymphadenectomy was carried out for advanced nodal involvement in four patients and for locally advanced disease infiltrating the pelvic wall in six patients. In all 10 patients, local pelvic recurrence was reported within the first year of follow-up (4).

In another study, post-operative outcome was reported for primary radical cystectomy in 20 T4 bladder cancer patients (of which seven cases were T4b). The authors concluded that primary cystectomy for T4 bladder cancer was technically feasible and had a very tolerable therapy-related morbidity and mortality (5).
8.2 Conclusions and recommendations for non-resectable tumours

Conclusions
Primary radical cystectomy in T4b bladder cancer is not a curative option.
If there are symptoms, radical cystectomy may be a therapeutic/palliative option.
Intestinal or non-intestinal forms of urinary diversion can be used with or without palliative cystectomy.

8.3 Supportive care
Severe, localised problems can occur in patients with invasive, non-operable bladder cancer and those in whom cystectomy has not been performed because of metastatic disease. These problems include pain, bleeding, voiding problems and obstruction of the upper urinary tract (UUT).

Obstruction of the UUT
Unilateral (best kidney) or bilateral nephrostomy tubes provide the easiest solution for UUT obstruction, but patients find the tubes are inconvenient and prefer ureteral stenting. However, stenting can be difficult to achieve and stents must be regularly replaced. There is also the risk of stent obstruction or displacement. Another possible solution is the possibility of a urinary diversion with, or without, a palliative cystectomy.

Bleeding and pain
In the case of bleeding, first screen the patient for coagulation disorders or review the patient’s use of anticoagulant drugs. Transurethral (laser) coagulation may be difficult in a bladder full of tumour or with a bleeding tumour. Intravesical rinsing of the bladder with 1% silver nitrate or 1-2% alum can be effective (12), and can usually be done without any form of anaesthesia. The instillation of formalin (2.5-4% during 30 minutes) is a more aggressive and more painful procedure, requiring general or regional anaesthesia. Formalin instillation also has a higher risk of side effects, e.g. bladder fibrosis, but is more likely to control the bleeding (13). Vesicoureteral reflux should be excluded to prevent renal complications.

Radiation therapy is another common strategy for control of bleeding, which is also used to control pain. In an older report, haematuria and pain control were 59% and 73%, respectively (14). Irritative bladder and bowel complaints due to irradiation are possible but are usually mild. Non-conservative options are embolisation of specific arteries in the small pelvis, with success rates as high as 90% (15). Radical surgery is a last resort and includes cystectomy and diversion.

8.4 References

9. NEOADJUVANT / ADJUVANT RADIOTHERAPY IN MUSCLE-INVASIVE BLADDER CANCER

Contrary to literature addressing radiotherapy prior to surgical intervention for muscle-invasive bladder cancer, data discussing findings for adjuvant radiotherapy after radical cystectomy are extremely scarce and outdated and relate mostly to non-urothelial cancer only (1). Possibly also due to late gastro-intestinal complications, post-operative radiotherapy has never been widely used. With the availability of equipment allowing for more precise targeting resulting in less damage to surrounding tissue, there may be reason to revisit this option in the future (2,3).

9.1 Pre-operative radiotherapy

9.1.1 Retrospective studies

Several retrospective studies have looked at the effect of pre-operative radiotherapy in patients with bladder cancer.

- The largest retrospective series (n = 526) showed that pre-operative radiotherapy at a dose of 50 Gy resulted in downstaging in 73% of cT3 patients versus 29% of patients who were not given pre-operative radiotherapy (4,5). Local control improved from 72% to 91% in pT3b patients (n = 91), but not in pT2 or pT3a patients, while overall survival improved from 40% to 52%.

- The results of a non-randomised study comparing 40 Gy vs. 5-20 Gy vs. no radiotherapy showed that only 40 Gy pre-operative radiotherapy reduced the risk of local recurrence from 27% to 11% and improved survival from 21% to 63% (6).

- Overall, nearly all retrospective studies of pre-operative radiotherapy at doses of 40-50 Gy, followed after 4-6 weeks by cystectomy, showed (4-12):
- downstaging of the tumour stage (40-65% of patients);
- lower risk of local recurrence (10-42%);
- improved survival (11-12%).

- Some studies showed that an improvement in local control was highest for T3b tumours (5-7).
- Other studies showed that achievement of a pathological complete remission (pCR) was a prognostic factor for survival (6-8).
- One retrospective study (8) found no significant increase in toxicity due to pre-operative radiotherapy (10% vs. 3%).

9.1.2 Randomised studies
There have been six published randomised studies investigating pre-operative radiotherapy.

- The largest randomised trial (n = 234 evaluable patients) administered pre-operative radiotherapy at a dose of 45 Gy in fractions of 1.8-2.2 Gy in muscle-invasive tumours. The results showed a significant increase in pCR (9% to 34%) in favour of pre-operative radiotherapy and no significant increase in 5-year survival of 33% to 45% (13). In patients not given adjuvant chemotherapy, survival was significantly better in patients given pre-operative radiotherapy (25-52%). Pathological complete remission was a prognostic factor for better survival. A major limitation was the exclusion from the analysis of almost 50% of patients because they did not receive the planned treatment.
- The Southwest Oncology Group (SWOG) trial (n = 124), which used a pre-operative dose of 5 x 4 Gy, did not show a survival advantage (14).
- An Egyptian study in patients with bladder cancer caused by bilharzia (predominantly squamous cell carcinoma, n = 92) showed a significant survival advantage for > T3 tumours, but a marginal and nonsignificant difference for the whole group (15).
- A small, randomised study of 44 patients (16) showed a significant increase in pCR (18-55%) and a small increase in 5-year survival (61-72%, not significant), but the results were limited by a small patient population and differing radiotherapy schedules (32-54 Gy).
- In another small, three-armed study (n = 72), patients were randomised between surgery, surgery with pre-operative radiotherapy (45 Gy in 4-5 weeks) and radiotherapy alone (50-60 Gy in 4-6 weeks) (17). Pre-operative radiotherapy resulted in 24% of patients achieving pCR. There were no significant differences in survival or toxicity between the three arms.
- There was no reported increase in toxicity due to pre-operative radiotherapy in any of the above-mentioned studies.
- The effect on the local recurrence rate was not specifically documented in any of the studies.
- Three of the randomised studies looked at downstaging and found an increase in pCR following pre-operative radiotherapy from 9% to 34% (10), 0% to 24% (14) and from 18% to 55% (16).
- Local recurrences were not reported (13,17), nor were they similar in any of the randomised studies (16).
- All five randomised studies looked at survival. The largest study found a significant survival advantage from 25% to 52% in those patients who did not receive adjuvant chemotherapy (13). The Egyptian study found a survival advantage only for T3 patients or higher (15). No study found a significant survival advantage for the whole group.
- A meta-analysis of the randomised trials on the value of pre-operative radiotherapy showed an odds ratio for the difference in 5-year survival of 0.71 (95% CI: 0.48-1.06). However, the meta-analysis was potentially biased by the many patients in the largest trial, who did not receive the planned treatment. When the results of the largest trial were excluded, the odds ratio became 0.95 (95% CI: 0.57-1.55), indicating that improved survival with pre-operative radiotherapy had not been proven (18,19).
- The sixth RCT was not included in the meta-analysis (18) since its findings deviated from all the others. Furthermore, the follow-up period was only two years (20).

9.1.3 Effect of pre-treating patients with neoadjuvant radiotherapy before cystectomy
A recent study compared the long-term outcome of pre-treating patients before cystectomy with neoadjuvant radiotherapy (n = 90) vs. not pre-treating with radiotherapy (n = 97). The clinical stage of tumours was T1-3. Downstaging to T0 after cystectomy occurred in 7% (7/97) without radiotherapy vs. 57% (51/90) with radiotherapy. In cT3 tumours, these results were 0% (0/16) vs. 59% (19/34), respectively. Downstaging resulted in a longer PFS. In cT3 tumours, there was also a significant longer disease-specific survival. However, the results are limited by the small patient numbers and the retrospective nature of the study.

Another recent retrospective study on neoadjuvant radiotherapy also found a survival advantage, though the results were also limited (21).

10. BLADDER-SPARING TREATMENTS FOR LOCALISED DISEASE

10.1 Transurethral resection of bladder tumour (TURB)
When patients with an initially invasive bladder cancer, presenting with pT0 or pT1 status at second resection, are selected for transurethral resection of bladder tumour (TURB) alone, about half of them will have to undergo radical cystectomy for recurrent muscle-invasive cancer, with a disease-specific death rate ranging up to 47% within this group (1,2).

A disease-free status at re-staging TUR appears to be crucial in making the decision not to perform radical cystectomy (3,4). A prospective study by Solsona et al. (3) included 133 patients with a radical TUR and negative biopsies, and recently reported 15 year follow-up (5). Patients had regular cystoscopy and biopsies, and were treated additionally according to their findings. In all, only 6.7% were understaged during the initial TURB, 30% had recurrent NMIBC and went on to intravesical therapy, and 30% (n=40) progressed, of which 27 died of bladder cancer. This results in a cancer-specific survival (CSS) of 81.9%, 79.5% and 76.7%, and a progression-free survival (PFS) with intact bladder of 75.5%, 64.9%, 57.8%, after 5, 10 and 15 years respectively.

TUR alone is only possible as a therapeutic option if tumour growth is limited to the superficial muscle layer and if re-staging biopsies are negative for residual tumour (6). TUR alone should only be considered as a therapeutic option when the patient is unfit for cystectomy or a multimodality bladder-preserving approach, or refuses open surgery (7).

10.2 External beam radiotherapy (EBRT)

The target field usually comprises the bladder only, with a safety margin of 1.5-2 cm to allow for unavoidable organ movements (1-4). Any beneficial effect with larger pelvic fields has not been demonstrated. The target dose for curative radiotherapy for bladder cancer is 60-66 Gy, with a subsequent boost using external radiotherapy or interstitial brachytherapy. The daily dose is usually 1.8-2 Gy, and the course of radiotherapy should not extend beyond 6-7 weeks to minimise the repopulation of cancer cells. The use of modern standard radiotherapy techniques results in major, related, late morbidity of the urinary bladder or bowel in less than 5% of tumour-free patients (5-9). As well as the response to radiotherapy, important prognostic factors for outcome include:

- tumour size;
- hydronephrosis;
- completeness of the initial TURB.

Overall, 5-year survival rates in patients with MIBC range between 30% and 60%, depending on whether they have a complete response (CR) following radiotherapy. Cancer-specific survival rates are between 20% and 50% (10-14).

Prognostic factors for success were investigated in an Italian single institution series of 459 irradiated patients, including approximately 30% of unfit T1 patients, with 4.4 years average follow-up. Significant factors were found in a multivariate survival analysis to be:

- age;
- T category (for all end points);
- tumour dose (only for failure-free survival) (15).

Based on available trials, a Cochrane analysis has demonstrated that radical cystectomy has an overall survival benefit compared to radiotherapy (16).

External radiotherapy can be an alternative treatment in patients unfit for radical surgery, as demonstrated in a group of 92 elderly or disabled patients with T2-4 N0-1 M0 bladder cancer and a median age of 79 years. The
total dose given was 55 Gy in 4 weeks. The cystoscopic complete remission rate at 3 months was 78%, 3-year local control rate 56%, and 3-year overall survival 36%. Pre-treatment bladder capacity was demonstrated in 81% of patients (17).

Similar long-term results were reported by Chung et al (18). Three hundred and forty patients with MIBC were treated with EBRT alone, EBRT with concurrent chemotherapy, or neoadjuvant chemotherapy followed by EBRT. The overall CR was 55% and the 10 year DSS and OS were 35% and 19% respectively. Complete response was 64%, 79%, and 52% after EBRT alone, concurrent chemotherapy (n=36), and neoadjuvant chemotherapy (n=57) respectively, although in this last group most patients had T3 and T4 tumours. Younger age, lower tumour stage and absence of CIS were associated with a significant improvement in survival. For example, in the T2 group, 5 year OS was 44% and DSS was 58%. A relapse within 2 to 3 years was a bad prognostic sign. The authors concluded that EBRT monotherapy was an option only in highly selected patients.

10.3 Chemotherapy
Chemotherapy alone rarely produces durable CRs. In general, a clinical complete response rate of up to 56%, as reported in some series, must be weighed against a staging error of > 60% (1-2). Response to chemotherapy is a prognostic factor for treatment outcome and eventual survival (3), though it may be confounded by patient selection.

Several groups have reported the effect of chemotherapy on resectable tumours (neoadjuvant approach), as well as unresectable primary tumours (4-7). Neoadjuvant chemotherapy with 2-3 cycles of methotrexate, vinblastine, adriamycin plus cisplatin (MVAC) or cisplatin, methotrexate plus vinblastine (CMV) has led to a downstaging of the primary tumour in different prospective series (4-6). Pathological complete responses of bladder primary tumours were reached in 12-50% of patients after MVAC and in 12-22% of patients after gemcitabine/cisplatin (GC) in phase II and phase III trials (4-6,8-16). Contemporary series with GC followed by radical cystectomy reported inferior pT0 rates, which may have been related to a lack of dose density and inappropriate delay of surgery (17). As for bladder preservation, response is evaluated by cystoscopy and CT-imaging only, followed by close surveillance. This approach is prone to an imminent staging error, which can put the patient at risk for local recurrence and/or consecutive metastatic disease.

For very selected patients, a bladder-conserving strategy with TUR of the bladder and systemic cisplatin-based chemotherapy, preferably with MVAC, may allow long-term survival with intact bladder (18). However, this approach cannot be recommended for routine use.

10.4 Multimodality bladder-preserving treatment

Recent organ-preservation strategies combine TURB, chemotherapy and radiation (1,2). The rationale for performing TURB and radiation is to achieve local tumour control. Application of systemic chemotherapy, most commonly as methotrexate, cisplatin and vinblastine (MCV), aims at the eradication of micrometastasis. Many protocols use cisplatin and/or 5-FU and, recently, gemcitabine with radiation, because of their established role as radiosensitisers. Cisplatin-based chemotherapy in combination with radiotherapy, following TURB, results in a complete response rate of 60-80%.

In a recent, small, phase 1-2 study the value of gemcitabine in multimodality treatment was emphasised, with a 5 year OS of 70.1% and DSS of 78.9% (3).

Another recent study with a mean follow-up of 42 months compared TURB + radiochemotherapy (n=331) with TURB + radiotherapy (n=142) (4). The overall CR was high (70.4%). However, the radiochemotherapy group had a clear survival advantage (median survival 70 months) compared to the radiotherapy group (median survival 28.5 months). Long-term results were dependent on stage, lymphatic invasion (LVI), residual tumour status and initial response at restaging TUR.

The importance of the radicality of the initial TUR was also confirmed in a recent Japanese study with 82 patients treated with TURB and chemoradiotherapy (5). Initial pCR rate was relatively low (39%) in the absence of a radical initial TURB. Still, clinical CR (84%) and survival data were high (5 year OS 77.7%, 5 year PFS 64.5%), although this included salvage treatment. Primary cT2 patients showed a significant improvement in survival compared to cT3-4 and recurrent cases.

Several other smaller recent series confirm the potential of multimodality protocols (6-9). Five year OS rates around 70% are reported. However, protocols differ for each study, as does patient selection. Recurring patients usually do badly, and so do patients with tumours progressing from NMIBC to MIBC. Low stage and complete TUR remain important prognostic variables.

It is recommended that early cystectomy is performed in individuals who do not achieve a complete response following combination therapy. About 40-45% of these patients may survive with an intact bladder at 4-5 years (2).

A comparable long-term survival rate of 50-60% at 5 year follow-up is reported by both multimodality bladder-preserving trials and cystectomy series. However, these therapeutic approaches have never been directly compared and patients in multimodality series are highly selected (2,10-12). A bladder-preserving multimodality strategy requires very close multidisciplinary co-operation and a high level of patient compliance. Even if a patient has shown a complete response to a multimodality bladder-preserving strategy, the bladder remains a potential source of recurrence. About half of patients can be expected to survive with their native bladder intact. A T0 status at repeat TUR after the initial transurethral resection of the primary tumour, followed by chemotherapy in combination with radiotherapy, was identified as a prognostically important variable. However, even the latter patients are at a life-long risk of developing intravesical tumour recurrences and need meticulous surveillance and multiple invasive procedures. It has been postulated that a delay in radical cystectomy due to an initial bladder-preserving approach increases the risk of lymph node metastases to a lymph node positive rate of 26% when cystectomy becomes necessary due to treatment failure.
10.4.1 Conclusions and recommendations for multimodality treatment in muscle-invasive bladder cancer

Conclusions

| LE | In a highly selected patient population, long-term survival rates of multimodality treatment are comparable to those of early cystectomy. |
| 3 |
| 2b | Delay in surgical therapy can compromise survival rates. |

Recommendations

| GR | Transurethral resection of bladder tumour alone cannot be offered as a standard curative treatment option in most patients. |
| B |
| B | Radiotherapy alone is less effective than surgery and is only recommended as a therapeutic option when the patient is unfit for cystectomy or a multimodality bladder-preserving approach. |
| B | Chemotherapy alone is not recommended as primary therapy for muscle-invasive bladder cancer. |
| A | Surgical intervention or multimodality treatment are the preferred curative therapeutic approaches since they are more effective than radiotherapy alone. |
| B | Multimodality treatment could be offered as an alternative in selected, well-informed, well selected and compliant patients, especially for whom cystectomy is not an option. |

10.4.2 References

11. ADJUVANT CHEMOTHERAPY

Adjuvant chemotherapy for patients after radical cystectomy with pT3/4 and/or lymph node positive (N+) disease without clinically detectable metastases (M0) is under debate (1,2). The benefits of chemotherapy in the adjuvant setting include:

- Chemotherapy is administered after accurate pathological staging.
- Overtreatment in patients at low risk for micrometastases is avoided.
- No delay in definitive surgical treatment, especially in patients not sensitive to chemotherapy.

The drawbacks of adjuvant chemotherapy are:

- Assessment of in vivo chemosensitivity of the tumour is not possible.
- Delay or intolerability of chemotherapy, due to post-operative morbidity.

There is not enough evidence in favour of the routine use of adjuvant chemotherapy (2,8). To date, there have been only five published randomised trials of adjuvant chemotherapy (3-7) and one meta-analysis (8), with updated individual patient data from six trials and a total of only 491 patients for survival analysis. Furthermore, all these trials were suboptimal with serious deficiencies, including low sample size (underpowered), substandard chemotherapy, early stopping of patient entry, and flaws in design and statistical analysis, including irrelevant endpoints or a lack of recommendations concerning salvage chemotherapy for relapse or metastases (2). The data are not convincing enough to give an unequivocal recommendation for the use of adjuvant chemotherapy.

From the evidence so far available, it is unclear whether immediate adjuvant chemotherapy or chemotherapy at the time of relapse is superior or if the two approaches are equivalent with respect to the endpoint overall survival. In recent trial updates, cisplatin-based combination chemotherapy was able to produce long-term disease-free survival, even in metastatic disease, albeit mainly in patients with lymph node metastases only, and with a good performance status (9-11).

Patients with extravesical and/or node positive disease following cystectomy should be enrolled in clinical trials whenever possible. In non-protocol-eligible patients, adjuvant cisplatin-based chemotherapy is an option provided the patient is well informed about the scarce data available.

Published trials of randomised adjuvant chemotherapy have used three to four cycles of CMV (cisplatin, methotrexate, vinblastine), CISCA (cisplatin, cyclophosphamide, and adriamycine), MVA(E)C (methotrexate, vinblastine, adriamycine or epirubicine, and cisplatin) and CM (cisplatin, methotrexate) (12). There is no evidence that more modern or carboplatin-containing chemotherapy combinations are as effective. Patients ineligible for cisplatin should not receive adjuvant chemotherapy.

12. METASTATIC DISEASE

Approximately 30% of patients with urothelial cancer present with muscle-invasive disease, and about half relapse after radical cystectomy, depending on the pathological stage of the primary tumour and the nodal status. Local recurrence accounts for ~30% of relapses, whereas distant metastases are more common. About 10-15% of patients are already metastatic at diagnosis (1). Before the development of effective chemotherapy, patients with metastatic urothelial cancer rarely had a median survival that exceeded 3-6 months (2).

12.1 Prognostic factors and treatment decisions

Outcome of chemotherapy depends on patient-related factors and pre-treatment disease. Prognostic factors for response and survival have been established. In a multivariate analysis, Karnofsky performance status (PS) of ≤ 80% and presence of visceral metastases were independent prognostic factors of poor survival after treatment with MVAC (methotrexate, vinblastine, Adriamycin and cisplatin). These so-called Bajorin prognostic factors (3) have also been validated for newer combination chemotherapy regimens (4,5) and carboplatin combinations (6). These prognostic factors are crucial for assessing phase II study results and stratifying phase
Ill trials (7,8). Additional data on the prognostic value of elevated alkaline phosphatase and the number of disease sites (more or less than three) have been generated prospectively (9). A retrospective analysis showed that, in elderly patients, Eastern Cooperative Oncology Group (ECOG) PS 2-3 and haemoglobin < 10 mg/dL were independent predictors of poor survival (9). Age itself has no impact on response or toxic events (10).

For patients refractory to or progressing shortly after platinum-based combination chemotherapy, four prognostic groups have been established, based on three adverse factors that developed in patients treated with vinflunine and validated in an independent data set: Hb < 10 g/dL; presence of liver metastases; and ECOG PS ≥ 1 (11).

12.1.1 Comorbidity in metastatic disease
Comorbidity is defined as “the presence of one or more diseases in addition to an index disease” (see Chapter 7). Patients with a history of cancer have an average of three co-morbid conditions and comorbidity is the rule rather than the exception. Incidence and prevalence of comorbidity increase with age. Comorbidity is an important predictor of clinical outcome (12). However, patients with comorbidity are mostly excluded from clinical trials (13).

In several studies, comorbidity was predictive of 1-5-year mortality rates, which was only partly true for age and sex.

</tbody>
</table>

Comorbidity increases with age. However, chronological age does not necessarily correlate with functional impairment. Physiological impairment varies substantially between individuals. There are several definitions by which patients can be selected as potentially fit or unfit for chemotherapy, but age is not among them.

12.1.2 Not eligible for cisplatin (unfit)
The European Organisation for Research and Treatment of Cancer (EORTC) conducted the first randomised phase II/III trial for urothelial carcinoma patients who were unfit for cisplatin chemotherapy (14). Their definitions are:
- fit: GFR > 60 mL/min and PS 0-1
- unfit: GFR < 60 mL/min and/or PS 2

A further survey of patients with metastatic urothelial cancer classified patients unfit for cisplatin-based chemotherapy who had: PS > 1; GFR > 60 mL/min; grade ≥ 2 audiometric loss and peripheral neuropathy; and New York Heart Association (NYHA) class III heart failure (15).

More than 50% of patients with urothelial cancer are not eligible for cisplatin-based chemotherapy (16-19).

Renal function assessment is of utmost importance in the urothelial cancer population. Calculation of creatinine clearance (CrCl) (24-h urine collection) with current formulae tends to underestimate clearance in patients aged > 65 years compared to measured CrCl (16,21).

12.2 Single-agent chemotherapy
Response rates to single-agent, first-line chemotherapy have varied. The most robust data have shown a response rate of about 25% for first- and second-line gemcitabine in several large phase II trials (32-39).

Responses with single agents are usually short-lived and complete responses are rare. Of note, no long-term disease-free survival has been reported with single-agent chemotherapy. The median survival in such patients is only 6-9 months. Patients with WHO PS 3-4, with or without additional negative prognostic factors, are not expected to benefit from combination chemotherapy. The most appropriate approach for this patient group is best supportive care (BSC) or, at most, single-agent chemotherapy.

12.3 Standard first-line chemotherapy for fit patients
Cisplatin-containing combination chemotherapy has been the standard of care since the late 1980s. MVAC has been proven superior to cisplatin monotherapy and CISCA (cisplatin, cyclophosphamide and Adriamycin)
(8,30) and, more recently, to cisplatin/docetaxel (31). MVAC and gemcitabine/cisplatin (GC) have prolonged survival up to 14.8 and 13.8 months, respectively compared to cisplatin monotherapy and CISCA (32-34). Neither of the two combinations is superior to the other, but equivalence has not been tested. Response rates were 46% and 49% for MVAC and GC, respectively. The long-term survival results have confirmed the anticipated equivalence of the two regimens (9). The major difference between the above-mentioned combinations is toxicity. The lower toxicity of GC (34) has resulted in it becoming a new standard regimen (35). MVAC is better tolerated when combined with granulocyte colony stimulating factor (G-CSF) (31,35).

High-dose intensity MVAC (HD-MVAC) with G-CSF is less toxic and more efficacious than standard MVAC in terms of dose density, complete response, and 2-year survival rate. However, there is no significant difference in median survival between the two regimens (36,37).

All disease sites have been shown to respond to cisplatin-based combination chemotherapy, but responses have been reported most often in lymph nodes. A response rate of 66% and 77% with MVAC and HD-MVAC, respectively, has been reported in retroperitoneal lymph nodes vs. 29% and 33% at extranodal sites (36). The disease sites also have an impact on long-term survival. In lymph-node-only disease, 20.9% of patients were alive at 5 years compared to only 6.8% of patients with visceral metastases (9).

Further intensification of treatment using the new PCG triple regimen (paclitaxel, cisplatin and gemcitabine) did not result in a significant improvement in OS in the intent-to-treat (ITT) population of a large randomised phase III trial, comparing PCG triple regimen to gemcitabine/cisplatin (38). However, the overall response rate (ORR) was higher with the triple regimen (56% vs. 44%; P=0.0031), the trend for OS improvement in the ITT population (15.8 vs. 12.7 months; HR=0.85, P=0.075) became significant in the eligible population and in the post-hoc analysis of patients who had primary bladder tumour. PCG is one new option for first-line treatment of UC.

Adding paclitaxel to GC did not induce major additional side effects. G4 neutropenia was more common (35.8% vs. 20% for GC), as was febrile neutropenia (13.2% vs. 4.3%), and the need for G-CSF was higher (17% vs. 11%). GC alone caused more G4 thrombocytopenia and thrombocytopenia-induced bleeding (11.4% vs. 6.8%).

12.4 Carboplatin-containing chemotherapy in fit patients
Carboplatin-containing chemotherapy is not equivalent to cisplatin combinations, and should not be considered interchangeable or standard.

Several randomised phase II trials of carboplatin vs. cisplatin combination chemotherapy have produced lower CR rates and shorter OS for the carboplatin arms (49-52).

12.5 Non-platinum combination chemotherapy
Different combinations of gemcitabine and paclitaxel have been studied as first- and second-line treatments. Apart from severe pulmonary toxicity with a weekly schedule of both drugs, this combination is well tolerated and produces response rates between 38% and 60% in both lines. Non-platinum combination chemotherapy has not been compared to standard cisplatin chemotherapy in randomised trials, therefore, it is not recommended for first-line use in patients who are fit enough (29,43-49).

12.6 Chemotherapy in patients unfit for cisplatin
Up to 50% of patients are ineligible for cisplatin-containing chemotherapy, either because of poor PS and/or impaired renal function, or because of comorbidity that prevents high-volume hydration (50,51). The first randomised phase II/III trial in this setting was conducted by EORTC and compared methotrexate/carboplatin/vinblastine (M-CAV) and carboplatin/gemcitabine (GemCarbo) in patients unfit for cisplatin. Both regimens were active. Severe acute toxicity (SAT) was 13.6% in patients treated with GemCarbo vs. 23% with M-CAV, while the ORR was 42% for GemCarbo and 30% for M-CAV. Further analysis showed that in patients with PS 2 and impaired renal function, combination chemotherapy provided limited benefit (52). The ORR and SAT were both 26% for the former group, and 20% and 24%, respectively, for the latter group (52). Recent phase III data have confirmed these results (53).

12.7 Second-line treatment
Second-line chemotherapy data are highly variable and prognostic factors have been established only recently (see 12.1, [11]).

A reasonable strategy may be to re-challenge former cisplatin-sensitive patients if progression occurs at least
6-12 months after first-line cisplatin-based combination chemotherapy.

Second-line response rates of paclitaxel (weekly), docetaxel, oxaliplatin, ifosfamide, topotecan, pemetrexed, lapatinib, gefitinib and bortezomib have ranged between 0% and 28% in small phase II trials (64-72). Although gemcitabine has also shown excellent response rates in second-line use (22,26-29,63,64), most patients already receive this drug as part of their front-line treatment.

Paclitaxel/gemcitabine have shown response rates of 38-60%, depending on patient selection. No adequate randomised phase III trial has been conducted to assess the true value of this second-line combination (2,44,48).

Vinflunine, a novel third-generation vinca alkaloid, has shown objective response rates of 18% and disease control in 67% of patients (65). A recent randomised phase III trial has compared vinflunine plus best supportive care against BSC alone in patients progressing after first-line treatment with platinum-containing combination chemotherapy for metastatic disease (66). The results showed a modest ORR (8.6%), a clinical benefit with a favourable safety profile and, most importantly, a survival benefit in favour of vinflunine, which was statistically significant in the eligible patient population (not in the ITT population). For second-line treatment of advanced or metastatic urothelial cancer, this trial reached the highest level of evidence ever reported. Currently, vinflunine is the only approved second-line treatment; any other treatment should take place in the context of clinical trials.

12.8 Low-volume disease and post-chemotherapy surgery
With cisplatin-containing combination chemotherapy, excellent response rates may be obtained in patients with lymph node but not other metastases, good PS, and adequate renal function, including a high degree of CRs, with up to 20% of patients achieving long-term disease-free survival (9,37,67,68). Stage migration may play a role in this positive prognostic development. A retrospective study of post-chemotherapy surgery after a partial or complete response has indicated that surgery may contribute to long-term disease-free survival in selected patients (69-71).

12.9 Treatment of bone metastases
The prevalence of metastatic bone disease (MBD) in patients with advanced/metastatic urothelial cancer is 30-40% (72). Skeletal complications due to MBD have a detrimental effect on pain and quality of life and are also associated with increased mortality (73). Bisphosphonates reduce and delay skeletal-related events (SREs) due to bone metastases by inhibiting bone resorption. In a small pilot study in patients with bladder cancer, SREs caused by bone metastases were delayed (74). Denosumab is a fully human monoclonal antibody that binds to and neutralises RANKL (receptor activator of nuclear factor-κB ligand), thereby inhibiting osteoclast function and preventing generalised bone resorption and local bone destruction. Denosumab is not inferior to zoledronic acid (ZA) in preventing or delaying SREs in patients with advanced MBD, including patients with urothelial carcinoma (75). Denosumab has recently been approved by the European Medicines Agency (EMA) for treatment of patients with bone metastases from solid tumours. Patients with MBD, irrespective of the cancer type, should be considered for bone-targeted treatment (73).

Patients treated with ZA or denosumab should be informed about possible side effects and receive prophylactic treatment for jaw osteonecrosis and hypocalcaemia, which is more common with denosumab. Aggressive calcium and vitamin D supplementation is recommended. Dosing regimens of ZA should follow regulatory recommendations and should be adjusted according to pre-existing medical conditions (86). For denosumab, no dose adjustments are required for variations in renal function.

12.10 Conclusions and recommendations for metastatic disease

<table>
<thead>
<tr>
<th>Conclusions</th>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>In a first-line setting, PS and the presence or absence of visceral metastases are independent prognostic factors for survival.</td>
<td>1b</td>
</tr>
<tr>
<td>In a second-line setting, prognostic factors are: liver metastasis, PS and haemoglobin (&lt; 10 g/dL)</td>
<td>2</td>
</tr>
<tr>
<td>Cisplatin-containing combination chemotherapy can achieve median survival of up to 14 months, with long-term disease-free survival reported in ~15% of patients with nodal disease and good PS.</td>
<td>1b</td>
</tr>
<tr>
<td>Single-agent chemotherapy provides low response rates of usually short duration.</td>
<td>2a</td>
</tr>
<tr>
<td>Carboplatin combination chemotherapy is less effective than cisplatin-based chemotherapy in terms of complete response and survival.</td>
<td>2a</td>
</tr>
</tbody>
</table>
Non-platinum combination chemotherapy produced substantial responses in first- and second-line settings, but has not been tested against standard chemotherapy in patients who are fit or unfit for treatment.

There is no defined standard chemotherapy for unfit patients with advanced or metastatic urothelial cancer.

Vinflunine reached the highest level of evidence ever reported for second-line use.

Post-chemotherapy surgery after partial or complete response may contribute to long-term disease-free survival.

Zoledronic acid and denosumab have been approved for all cancer types including urothelial cancer, because they reduce and delay SREs in MBD.

---

**Recommendations**

**First-line treatment for fit patients:**

Use cisplatin-containing combination chemotherapy with GC, PCG, MVAC, preferably with G-CSF, or HD-MVAC with G-CSF.

Carboplatin and non-platinum combination chemotherapy is not recommended.

**First-line treatment in patients ineligible (unfit) for cisplatin:**

Use carboplatin combination chemotherapy or single agents.

For cisplatin-ineligible (unfit) patients, with PS2 or impaired renal function, as well as those with 0-1 poor Bajorin prognostic factors and impaired renal function, treatment with carboplatin-containing combination chemotherapy, preferably with gemcitabine/carboplatin is indicated.

**Second-line treatment:**

In patients progressing after platinum-based combination chemotherapy for metastatic disease, vinflunine should be offered. Alternatively, treatment within a clinical trial setting may be offered.

Zoledronic acid or denosumab is recommended for treatment of bone metastases.

---

*B Grade A recommendation is weakened by a problem of statistical significance.*

---

**12.11 Biomarkers**

Modest disease control rates, with sporadic marked responses, in some patients with urothelial bladder cancer have led to the investigation of biomarkers for assessment of post-operative prognosis and the potential value of peri-operative chemotherapy, and as predictors of response to chemotherapy or its monitoring. Most of the biomarkers are associated with tumour angiogenesis. Small studies, usually retrospective, have investigated microvessel density, altered p53 tumour expression (87), serum vascular endothelial growth factor (88), urinary and tissue basic fibroblast growth factor (89), urinary (wild-type and mutant) and tissue fibroblast growth factor receptor-3 (90), and more recently, thrombospondin-1 (91), circulating tumour cells (92,93), and multidrug resistance gene expression (94). Although a few biomarkers have shown potential, none has sufficient evidence to support its routine clinical use (LE: 3).

---

**Recommendation on the use of biomarkers**

Currently, no biomarkers can be recommended in daily clinical practice because they have no impact on predicting outcome, treatment decisions or monitoring therapy in muscle-invasive bladder cancer.

*Upgraded following panel consensus.*

13. QUALITY OF LIFE

13.1 Introduction
The evaluation of health-related quality of life (HRQoL) considers physical, psychological, emotional and social functioning.

Several questionnaires have been validated for assessing HRQoL in patients with bladder cancer, including FACT (Functional Assessment of Cancer Therapy)-G (1), EORTC QLQ-C30 (2), EORTC QLQ-BLM (muscle-invasive bladder cancer module) (3), and SF (Short Form)-36 (4,5) and recently the BCI questionnaire specifically designed and validated for bladder cancer patients (6).

A psychometric test, such as the FACT-BL, should be used for recording bladder cancer morbidity. New intensive interviewing techniques have added valuable information to our knowledge of HRQoL, which greatly depends on patients’ individual preferences in life (7).

Unfortunately, most retrospective studies do not evaluate the association between HRQoL and bladder cancer-specific issues after cystectomy, such as day-time and night-time incontinence or potency. Furthermore, important co-variables, such as a patient’s age, mental status, coping ability and gender, have rarely been considered (8,9). It remains difficult to predict the impact of post-therapeutic symptoms because of individual differences in symptom tolerance.

13.2 Choice of urinary diversion
There is controversy about which type of urinary diversion is best for a patient’s HRQoL (10). Some studies have not demonstrated any difference in HRQoL (9,11,12). Nevertheless, most patients stated that, given a choice, they would still opt for an orthotopic diversion rather than an ileal conduit (13). Another study reported that, although urinary function is better in conduit patients, the urinary bother is the same in both diversion groups, resulting in the same HRQoL evaluation (14).
Due to improved surgical techniques in orthotopic bladder substitution, some recent studies are supportive of continent bladder substitutes (3,15-18). Two studies have shown a statistically significant difference in HRQoL in favour of neobladders (18,19). Patients with an orthotopic substitution had significantly better physical function and a more active lifestyle compared to patients with an ileal conduit. It is important to note that HRQoL parameters are independent prognostic factors for overall survival (20). Patients with a continent bladder-substitute generally scored more favourably than those with an incontinent diversion, as judged by body image, social activity and physical function (14,15,21).

### 13.3 Non-curative or metastatic bladder cancer

In non-curative or metastatic bladder cancer, HRQoL is reduced because of associated micturition problems, bleeding, pain and therefore disturbance of social and sexual life (22). There is limited literature describing HRQoL in bladder cancer patients receiving palliative care (23), but there are reports of bladder-related symptoms relieved by palliative surgery (24), radiotherapy (25), and/or chemotherapy (26).

Alternative definitive treatments of MIBC, e.g. trimodality bladder-sparing procedures, have shown similar survival times compared to cystectomy. However, the impact on HRQoL has been controversial (26-31).

### 13.4 Conclusions and recommendations for HRQoL

**Conclusions LE**

- No randomised, prospective HRQoL study has evaluated the different forms of definitive treatment for MIBC.

- In most patient groups studied, the overall HRQoL after cystectomy remains good, irrespective of the type of urinary diversion used. The suggestion that continent diversions are associated with a higher HRQoL, has not been sufficiently substantiated.

**Recommendations GR**

- The use of validated questionnaires is recommended to assess HRQoL in patients with MIBC.
- Unless a patient’s comorbidities, tumour variables and coping abilities present clear contraindications, a continent urinary diversion should be offered.
- Pre-operative patient information, patient selection, surgical techniques, and careful post-operative follow-up are the cornerstones for achieving good long-term results.
- Patients should be encouraged to take active part in the decision-making process. Clear and exhaustive information on all potential benefits and side-effects should be provided, allowing them to make informed decisions.

HRQoL = health-related quality of life; MIBC = muscle-invasive bladder cancer

### 13.5 References

14. FOLLOW-UP

An appropriate schedule for disease monitoring should be based on:
- natural timing of recurrence;
- probability of disease recurrence;
- functional deterioration at particular sites;
- possibilities of treatment of a recurrence (1).

Nomograms on cancer-specific survival following radical cystectomy have been developed and externally validated. However, their wider use cannot be recommended prior to further data (2-4).

Contemporary cystectomy series have demonstrated 5-15% probability of pelvic recurrence. Most recurrences manifest during the first 24 months, often within 6-18 months after surgery. However, late recurrences have occurred up to 5 years after cystectomy. Again, pTN and pN were predictive of the development of pelvic recurrence.

Patients have a poor prognosis after pelvic recurrence. Even with treatment, the median survival ranges from 4-8 months following diagnosis. Definitive therapy can sometimes provide prolonged survival, but in most cases provides significant palliation of symptoms. Treatment is with systemic chemotherapy, local surgery or radiotherapy.

14.1 Site of recurrence

14.1.1 Distant recurrences

Distant recurrences are seen in up to 50% of patients treated with cystectomy. Most recurrences occur in the first 24 months, although progression has been observed after more than 10 years (5). Again, pTN and pN were risk factors (6).
The most likely sites for distant recurrences are the lungs, liver and bones (7). Upper urinary tract recurrence is rarely seen (1.8-6.0%). However, when it develops, it usually does so within 28-49 months after cystectomy (8). Surveillance regimens often fail to detect tumours before symptoms develop. Radical nephro-ureterectomy can provide prolonged survival (9).

**14.1.2 Urothelial extravesical recurrences (see comment below)**

The incidence of secondary urethral tumours after radical cystectomy is 1.5-6.0% in males, with a mean recurrence-free interval of 13.5-39 months and a median survival of 28-38 months, of which > 50% died because of systemic disease.

Secondary urethral tumours are particularly likely to occur at 1-3 years after surgery. Prophylactic urethrectomy at the time of cystectomy is no longer justified in most patients. Independent predictors for urethral recurrence are: cystectomy for NMIBC, prostate involvement, and a history of previously recurrent NMIBC (8).

In women, the main risk factor is disease at the bladder neck (10). Many studies have demonstrated that the risk of urethral recurrence after orthotopic diversion (0.9-4%) (11-14) is significantly less than after non-orthotopic diversion (6.4-11.1%) (11,13).

There is little data and agreement about urethral follow-up, with some authors recommending routine surveillance with urethral wash cytology and urine cytology (14), and others doubting the need for routine urethral surveillance (12,15-17). Urethral washes and urine cytology do not appear to have any effect on survival (15,18,19). However, there is a significant survival advantage in males with urethral recurrence diagnosed asymptptomatically versus symptomatically, so follow-up of the male urethra is indicated in those patients at risk of urethral recurrence (8).

Treatment is influenced by the local stage and grade of a urethral occurrence:
- In CIS of the urethra, BCG instillations have shown success rates of 83% (14).
- In invasive disease, urethrectomy should be performed if the urethra is the only site of disease.
- In distant disease, systemic chemotherapy is indicated (7).

UUTTs occur in 1.8-6% of cases in contemporary series and represent the most common sites of late recurrence (3 years of disease-free survival following radical cystectomy). The median OS is 10-55 months, and 60-67% of patients will die of metastatic disease (8).

A recent meta-analysis found that 38% of UUT recurrence was diagnosed by follow-up investigation, whereas in the remaining 62% diagnosis was based on symptoms. When urine cytology was used in surveillance, the rate of primary detection was 7% and with UUT imaging it was 29.6% (22).

The meta-analysis made the following useful conclusions:
- Patients with superficial cancer have a probability of a UUT-TCC lesion twice as high as those with invasive disease.
- Multifocality increases the risk of recurrence by 3-fold and recurrence from 2 to 4-fold.
- Positive ureteral or urethral margins increase the risk by 7-fold.

14.1.4 Follow-up of functional outcomes and complications

Urinary-diversion related complications are detected in 45% of patients during the first 5 years of follow-up. This rate increases with time being more than 54% after 15 years of follow-up. Long-term follow-up of functional outcomes are desirable (8) (LE:3). Follow-up may stop after 15 years.

1. INTRODUCTION

The European Association of Urology (EAU) Guidelines Group on Muscle-invasive and Metastatic Bladder Cancer has prepared these guidelines to deliver current evidence-based information on the diagnosis and treatment of patients with primary urethral carcinoma (UC). When the first carcinoma in the urinary tract is detected in the urethra, this is defined as primary UC, in contrast to secondary UC, which presents as recurrent carcinoma in the urethra after prior diagnosis and treatment of carcinoma elsewhere in the urinary tract. Most often, secondary UC is reported after radical cystectomy for bladder cancer (1) (see Chapter 14 of the EAU Guidelines on Muscle-invasive and Metastatic Bladder Cancer [2]).

2. METHODOLOGY

A systematic literature search was performed to identify studies reporting urethral malignancies. Medline was searched using the controlled vocabulary of the Medical Subject Headings (MeSH) database, along with a free-text protocol, using one or several combinations of the following terms: adenocarcinoma, adjuvant treatment, anterior, chemotherapy, distal urethral carcinoma, lower, neoadjuvant, partial, penectomy, penile-preserving surgery, posterior, primary, proximal urethral carcinoma, radiotherapy, recurrence, risk factors, squamous cell carcinoma, survival, transitional cell carcinoma, urethra, urethrectomy, urethral cancer, urinary tract, and urothelial carcinoma. No randomised controlled trials (RCTs) were identified and articles were selected based on study design, treatment modality and long-term outcomes. Older studies (> 10 years) were considered if they contained historically relevant data or in the absence of newer data.

3. LEVEL OF EVIDENCE AND GRADE OF RECOMMENDATION

References in the text have been assessed according to their level of scientific evidence (LE), and guideline recommendations have been graded according to the listings in Tables 1 and 2, based on the Oxford Centre for Evidence-based Medicine Levels of Evidence (3). Grading aims to provide transparency between the underlying evidence and the recommendation given (3). Due to the fact that primary UC belongs to the family of rare cancers, most studies are retrospective, and recommendations given in these guidelines are mainly based on level 3 evidence.

*Modified from Sackett et al. (3).

It should be noted that when recommendations are graded, the link between the LE and grade of recommendation (GR) is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation when there are methodological limitations or disparity in published results.

Alternatively, the absence of a high level of evidence does not preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. There may be exceptional situations where corroborating studies cannot be performed - perhaps for ethical or other reasons - and in this case, unequivocal recommendations are considered helpful. Whenever this occurs, it is indicated in the text as
“upgraded based on panel consensus”. The quality of the underlying scientific evidence - although a very
important factor - has to be balanced against benefits and burdens, values and preferences, and costs when a
grade is assigned (4-6).

The EAU Guidelines Office does not perform structured cost assessments, nor can they address local/
national preferences in a systematic fashion. However, whenever these data are available, the Expert Panel will
include the information.

Publication history
This 2013 guidelines document on Primary Urethral Carcinoma is the first publication on this topic by the EAU.
This document was subjected to blinded peer review prior to publication.

Potential conflict of interest statement
The expert panel have submitted potential conflict of interest statements that can be viewed on the EAU
website: http://www.uroweb.org/guidelines/online-guidelines/.

4. **Epidemiology**

Primary UC is considered a rare cancer, accounting for < 1% of all malignancies (7) (ICD-O3 topography code: C68.0 [8]).

The RARECARE project, which has been set up to describe the epidemiology of rare urogenital cancers in 64 European population-based cancer registries (covering 32% of the population of the 27 Member States of the European Union (EU), has reported recently on 1,059 new cases of epithelial urethral tumours detected between 1995 and 2002 (9). In early 2008, the prevalence of UC in the 27 EU countries was 4,292 cases with an estimated annual incidence of 655 new cases. The age-standardised ratio was 1.1 per million inhabitants (1.6/million in men and 0.6/million in women; a male to female ratio of 2.9) (9). There were differences between European regions; potentially caused by registration or classification (9). Likewise, in an analysis of the Surveillance, Epidemiology and End Results (SEER) database, the incidence of primary UC peaked in the ≥ 75 years age group (7.6/1,000,000). The age-standardised rate was 4.3/million in men and 1.5/
/ million in women, and was almost negligible in those aged < 55 years (0.2/million) (10).

5. **Etiology and Risk Factors**

For male primary UC, various predisposing factors have been reported, including urethral strictures (11,12),
chronic irritation after intermittent catheterisation/urethroplasty (13-15), external beam irradiation therapy (16),
radioactive seed implantation (17), and chronic urethral inflammation/urethritis following sexually transmitted
diseases (i.e. condylomata associated with human papilloma virus 16) (18,19). In female UC, urethral diverticula
(20-22) and recurrent urinary tract infections (23) have been associated with primary carcinoma. Clear cell
adenocarcinoma may also have a congenital origin (24).
6. **HISTOPATHOLOGY**

Both the RARECARE project and SEER database have reported that urothelial carcinoma of the urethra is the predominant histological type of primary urethral cancer (54-65%), followed by squamous cell carcinoma (SCC; 16-22%) and adenocarcinoma (AC; 10-16%) (9,10). A recent SEER analysis of 2,065 men with primary urethral cancer (mean age: 73 years) found that urothelial carcinoma (78%) was most common, and SCC (12%) and AC (5%) were significantly less frequent (25). In women, a recent report of the National Cancer Registry of the Netherlands on primary urethral cancer reported that urothelial carcinoma occurred in 45% of cases, followed by AC in 29%, SCC in 19%, and other histological entities in 6% (26). Several other rare histological types of urethral malignancies have been also described in these studies.

7. **CLASSIFICATION**

7.1 **TNM staging system**

In men and women, UC is classified according to the 7th edition of the TNM classification (8) (Table 3). It should be noted that there is a separate TNM staging system for prostatic UC (8). Of note, for cancers occurring in urethral diverticulum stage T2 is not applicable as urethral diverticula are lacking periurethral muscle (27).

7.2 Tumour grade
The former WHO grading system of 1973 which differentiated urothelial carcinomas into three different grades (G1-G3) has been replaced by the grading system of 2004 that differentiates urothelial UC into PUNLMP, low grade and high grade. Non-urothelial UC is graded by a trinomial system that differentiates between well-differentiated (G1), moderately differentiated (G2), and poorly differentiated tumours (G3). Table 4 lists the different grading systems according to the WHO 1973 and 2004 systems (28).

Recommendation LE GR
Pathological staging and grading of primary UC should follow the 2009 TNM classification and WHO 2004 grading system. 3 B

8. SURVIVAL

8.1 Long-term survival after primary urethral carcinoma
According to the RARECARE project, the mean 1- and 5-year overall survival in patients with UC in Europe is 71% and 54%, respectively (9). With longer follow-up, a SEER analysis of 1,615 cases reported median 5- and 10-year overall survival rates of 46% and 29%, respectively. Cancer-specific survival at 5 and 10 years was 68% and 60%, respectively (10).

8.2 Predictors of survival in primary urethral carcinoma
In Europe, mean 5-year overall survival does not substantially differ between the sexes (9). Predictors of decreased survival in patients with primary UC are:
• Advanced age and race (≥ 65 years) (9,29)
• Stage, grade, nodal involvement and metastasis (25)
• Tumour size and proximal tumour location (25)
• Extent of surgical treatment and treatment modality (25, 29)
• Underlying histology (9,26,29)

Some limitations have to be taken into account in the interpretation of these results. In the Dutch study, the numbers were low (n = 91) (26). In the large SEER database (n = 2,046), therapy is not well specified in relation to survival (25). Finally, in contrast to the RARECARE project (9), the opposite findings were reported in the SEER database in relation to the role of histology on survival in male patients (29).

Conclusion LE
Risk factors for survival in primary UC are: age, tumour stage and grade, nodal stage, presence of distant metastasis, histological type, tumour size, tumour location, and type and modality of treatment. 3
9. DIAGNOSIS AND STAGING

9.1 History
When becoming clinically apparent, most patients (45-57%) with primary UC present with symptoms associated with locally advanced disease (T3/T4) (26,30). At initial presentation visible haematuria or bloody urethral discharge is reported in up to 62% of the cases. Further symptoms of locally advanced disease include an extraurethral mass (52%), bladder outlet obstruction (48%), pelvic pain (33%), urethrocystaneous fistula (10%), abscess formation (5%) or dyspareunia (30).

9.2 Clinical examination
In men, physical examination should comprise palpation of the extern genitalia for suspicious indurations or masses and digital rectal examination (31). In women, further pelvic examination with careful inspection and palpation of the urethra should be performed, especially in those with primary onset of irritative or obstructive voiding. In addition, bimanual examination, when necessary under general anaesthesia, should be performed for local clinical staging and to exclude the presence of colorectal or gynaecological malignancies.

Bilateral inguinal palpation should be conducted to assess the presence of enlarged lymph nodes, describing location, size and mobility (32).

9.3 Urinary cytology
The role of urinary cytology in primary UC is limited, and its sensitivity ranges between 55 and 59% (33). Detection rate depends on the underlying histological entity. In male patients, the sensitivity for urothelial carcinoma and SCC was reported to be 80% and 50%, respectively, whereas in female patients sensitivity was found to be 77% for SCC and 50% for urothelial carcinoma.

9.4 Diagnostic urethrocystoscopy and biopsy
Diagnostic urethrocystoscopy and biopsy enables primary assessment of a urethral tumour in terms of tumour extent, location and underlying histology (31). To enable accurate pathological assessment of surgical margins, biopsy sites (proximal/distal end) should be marked and sent together with clinical information to the pathologist. Careful cystoscopic examination is necessary to exclude the presence of concomitant bladder tumours (2). A cold-cup biopsy enables accurate tissue retrieval for histological analysis and avoids artificial tissue damage. In patients with larger lesions, transurethral resection (optionally in men under penile blood arrest using a tourniquet) can be performed for histological diagnosis. In patients with suspected urothelial carcinoma of the prostatic urethra or ducts, resectoscope loop biopsy of the prostatic urethra (at 5 and 7 o’clock positions from the bladder neck and distally around the area of the verumontanum) can contribute to an improved detection rate (34).

9.5 Radiological imaging
Radiological imaging of urethral cancer aims to assess local tumour extent and to detect lymphatic and distant metastatic spread. For local staging, there is increasing evidence that magnetic resonance imaging (MRI) is superior to computed tomography (CT) in terms of staging accuracy. Imaging for regional lymph node metastases should concentrate on inguinal and pelvic lymph nodes, using either MRI or CT. Distant staging should concentrate on chest and liver, with CT of the thorax and abdomen in all patients with invasive disease (≥ cT1N0M0 (35-39). If imaging of the remainder of the urothelium is required, then CT urography with an excretory phase (40).

9.6 Regional lymph nodes
In contrast to penile cancer, in which clinically enlarged lymph nodes at initial diagnosis are not uncommon due to inflammatory conditions (41), enlarged lymph nodes in urethral cancer often represent metastatic disease (42). In men, lymphatics from the anterior urethra drain into the superficial and deep inguinal lymph nodes and subsequently to the pelvic (external, obturator and internal iliac) lymph nodes. Conversely, lymphatic vessels of the posterior urethra drain into the pelvic lymph nodes. In women, the lymph of the proximal third drains into the pelvic lymph node chains, whereas the distal two-thirds initially drains into the superficial and deep inguinal nodes (43,44).

Nodal control in urethral cancer can be achieved either by regional lymph node dissection (31), radiotherapy (45) or chemotherapy (42). Currently, there is no clear evidence to support prophylactic bilateral inguinal and/or pelvic lymphadenectomy in all patients with urethral cancer. However, in patients with clinically enlarged inguinal/pelvic lymph nodes or invasive tumours, regional lymphadenectomy should be considered for initial treatment because cure might still be achievable with limited disease (31).
Conclusion

Patients with clinically enlarged inguinal or pelvic lymph nodes often exhibit pathological lymph node metastasis.

10. TREATMENT OF LOCALISED PRIMARY URETHRAL CARCINOMA

10.1 Treatment of localised primary urethral carcinoma in males

Previously, treatment of male anterior urethral cancer has followed the procedure for penile cancer, with aggressive surgical excision of the primary lesion with a wide safety margin (31). Distal urethral tumours exhibit significantly improved survival rates compared with proximal tumours (46). Therefore, optimising treatment of distal urethral cancer has become the focus of clinicians to improve functional outcome and quality of life, while preserving oncological safety. A retrospective series found no evidence of local recurrence, even with <5-mm resection margins (median follow-up: 17-37 months), in men with pT1-3N0-2 anterior UC treated with well-defined penis-preserving surgery and additional iliac/inguinal lymphadenectomy for clinically suspected lymph node disease (47). This suggests that prognosis is mainly determined by nodal stage. Similar results for the feasibility of penile-preserving surgery have been reported in other retrospective series (30,48).

<table>
<thead>

</tr>
</thead>
<tbody>
<tr>
<td>In localised anterior urethral tumours, penile-preserving surgery is an alternative to primary urethrectomy, if negative surgical margins can be achieved.</td>
<td>3</td>
<td>B</td>
</tr>
</tbody>
</table>

10.2 Treatment of localised urethral carcinoma in females

10.2.1 Urethrectomy and urethra-sparing surgery

In women with localised urethral cancer, to provide the highest chance of local cure, primary radical urethrectomy should remove all the periurethral tissue from the bulbocavernous muscle bilaterally and distally, with a cylinder of all adjacent soft tissue up to the pubic symphysis and bladder neck. Bladder neck closure and proximal diversion through appendico-vesicostomy for primary anterior urethral lesions has been shown to provide satisfactory functional results in women (31).

Many recent series have reported outcomes in women with mainly anterior urethral cancer undergoing primary treatment with urethra-sparing surgery or radiotherapy, compared to primary urethrectomy, with the aim of maintaining integrity and function of the lower urinary tract (49,50). In long-term series with median follow-up of 153-175 months, local recurrence rates in women undergoing partial urethrectomy with intraoperative frozen section analysis were 22-60%, and distal sleeve resection of >2 cm resulted in secondary urinary incontinence in 42% of patients who required additional reconstructive surgery (49,50). Ablative surgical techniques, that is, transurethral resection (TUR) or laser, used for small distal urethral cancer, have also resulted in a considerable local failure rate of 16%, with a cancer-specific survival rate of 50%. This emphasises the critical role of local tumour control in women with distal urethral cancer to prevent local and systemic progression (49).

10.2.2 Radiotherapy

In women, radiotherapy was investigated in several older long term series with a medium follow-up of 91-105 months (45,47). With a median cumulative dose of 65 Gy (range: 40-106 Gy), the 5-year local control rate was 64% and 7-year cancer-specific survival was 49% (45). Most local failures (95%) occurred within the first 2 years after primary treatment (47). The extent of urethral tumour involvement was found to be the only parameter independently associated with local tumour control but the type of radiotherapy (external beam vs. interstitial brachytherapy) was not (45). In one study, the addition of brachytherapy to external beam radiotherapy reduced the risk of local recurrence by a factor of 4.2 (51). Of note, pelvic toxicity in those achieving local control was considerable (49%), including urethral stenosis, fistula, necrosis, and haemorrhagic cystitis, with 30% of the reported complications graded as severe (45).

11. MULTIMODAL TREATMENT IN ADVANCED URETHRAL CARCINOMA

11.1 Preoperative cisplatinum-based chemotherapy

Recent retrospective studies have reported that modern cisplatin-based polychemotherapeutic regimens are effective in advanced primary urethral cancer, providing prolonged survival even in lymph-node-positive disease. Moreover, they have emphasised the critical role of surgery after chemotherapy for achieving long-term survival in patients with locally advanced urethral cancer. The largest retrospective series reported outcomes in 44 patients with advanced primary urethral cancer. Patients were subjected to specific cisplatinum-based polychemotherapeutic regimens according to the underlying histology. The overall response rate for the various regimens was 72%. The median overall survival of the entire cohort was 32 months. Of note, patients who underwent surgery after chemotherapy had significantly improved overall survival compared with those who were managed with chemotherapy alone (42).

11.2 Preoperative chemoradiotherapy in locally advanced squamous cell carcinoma of the urethra

The clinical feasibility of preoperative local radiotherapy with concurrent radiosensitising chemotherapy prior to surgery in locally advanced SCC has been reported in several case series (52-57). The largest and most recent series reported outcomes in 18 patients with primary locally advanced urethral cancer. A complete response to primary chemoradiotherapy was observed in 83% of the patients. The 5-year overall and disease-specific survival was 60% and 83%, respectively. Patients undergoing salvage surgery after chemoradiotherapy experienced a higher 5-year disease-free survival than those without salvage surgery (72% vs. 54%) (57).

12. TREATMENT OF UROTHELIAL CARCINOMA OF THE PROSTATE

Local conservative treatment with extensive TUR and subsequent Bacille-Calmette-Guérin (BCG) instillation is effective in patients with Ta or Tis prostatic UC (58,59). Likewise, patients undergoing TUR of the prostate prior to BCG experience improved complete response rates compared with those who do not (95% vs. 66%) (60). Risk of understaging local extension of prostatic urethral cancer at TUR is increased, especially in patients with ductal or stromal involvement (61). In smaller series, response rates to BCG in patients with prostatic duct involvement have been reported to vary between 57 and 75% (58,62). Some former series have reported superior oncological results for the initial use of radical cystoprostatectomy as a primary treatment option in patients with ductal involvement (63,64). In 24 patients with prostatic stromal invasion treated with radical cystoprostatectomy, a lymph node mapping study found that 12 patients had positive lymph nodes, with an increased proportion located above the iliac bifurcation (65).

13. FOLLOW-UP

**COMMENTARY:** Given the low incidence of primary urethral cancer, defined follow-up has not been investigated systematically so far. Therefore, it seems reasonable to tailor surveillance regimens according to the patients’ individual risk factors (Chapter 8.2). In patients undergoing urethra-sparing surgery, it seems prudent to advocate a more extensive follow-up with urinary cytology, urethrocytoscopy and cross-sectional imaging despite the lack of specific data.

21. ABBREVIATIONS USED IN THE TEXT 151
1. INTRODUCTION

1.1 Introduction
The European Association of Urology (EAU) Guidelines Group for Prostate Cancer have prepared this guidelines document to assist medical professionals assess the evidence-based management of prostate cancer. The multidisciplinary panel of experts include urologists, radiation oncologists, a medical oncologist, and a pathologist specialized in prostate cancer.

1.2 Data identification and evidence sources
The recommendations provided in the current guidelines are based on a systemic literature search performed by the panel members (1). MedLine, Embase, and Web of Science databases were searched to identify original articles, review articles and editorials addressing “epidemiology”, “risk factors”, “diagnosis”, “staging” and “treatment” of prostate cancer. The controlled vocabulary of the Medical Subject Headings (MeSH) database was used alongside a “free-text” protocol, combining “prostate cancer” with the terms “diagnosis”, “screening”, “staging”, “active surveillance”, “radical prostatectomy”, “external beam radiation”, “brachytherapy”, “androgen deprivation”, “chemotherapy”, “relapse”, “salvage treatment”, and “follow-up” to ensure sensitivity of the searches.

All articles published between January 2010 (previous update) and November 2011 were considered for review. The expert panel reviewed these records to select the articles with the highest evidence, according to a rating schedule adapted from the Oxford Centre for Evidence-based Medicine Levels of Evidence (1). Additionally, publications from the major urological (EAU, AUA) and oncological meetings (ASCO, ESMO, ASTRO) have been considered. Where possible, abstracts will be replaced by the full scientific publications when these become available. Also no major recommendations can be based on evidence from abstract only.

It must be emphasised that clinical guidelines present the best evidence available but following the recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, also taking individual circumstances and patient preferences into account.

1.3 Level of evidence and grade of recommendation
The level of evidence (LE) and grade of recommendation (GR) provided in this guideline follow the listings in Tables 1 and 2. The aim of grading the recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

<table>
<thead>
<tr>
<th>Level</th>
<th>Type of evidence</th>
</tr>
</thead>
<tbody>
<tr>
<td>1a</td>
<td>Evidence obtained from meta-analysis of randomised trials</td>
</tr>
<tr>
<td>1b</td>
<td>Evidence obtained from at least one randomised trial</td>
</tr>
<tr>
<td>2a</td>
<td>Evidence obtained from one well-designed controlled study without randomisation</td>
</tr>
<tr>
<td>2b</td>
<td>Evidence obtained from at least one other type of well-designed quasi-experimental study</td>
</tr>
<tr>
<td>3</td>
<td>Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports</td>
</tr>
<tr>
<td>4</td>
<td>Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities</td>
</tr>
</tbody>
</table>

*Modified from Sackett, et al. (1).

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and the grade of recommendation. The availability of RCTs may not necessarily translate into a grade A recommendation if there are methodological limitations or disparities in the published results. Conversely, an absence of high-level evidence does not necessarily preclude a grade A recommendation if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the reader. Whenever this occurs, it has been clearly indicated in the text with an asterisk as ‘upgraded based on panel consensus’. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned (2-4).
The EAU Guidelines Office does not perform cost assessments, nor can they address local/national preferences in a systematic fashion. However, whenever such data are available, the expert panels will include the information.

**Table 2: Grade of recommendation**

<table>
<thead>

### 1.4 Publication history

The Prostate Cancer Guidelines were first published in 2001, with partial updates achieved in 2003 and 2007, followed by a full text update in 2009. Also in 2011 and 2012 a considerable number of sections of the PCa guidelines were revised. This 2013 publication includes a number of updated chapters as detailed below.

Standard procedure for EAU publications includes an annual assessment of newly published literature in this field, guiding future updates.

An ultra-short reference document is being published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

**Summary of updated and new information**

- **Chapter 8 “Treatment: deferred treatment (watchful waiting)”**
  In section 8.2.1 (Watchful waiting), the findings of the PIVOT trial have been included.

- **Chapter 9 “Treatment Radical Prostatectomy”**
  The literature has been updated and additional recommendations for lymph node dissection have been included in section 9.7 (Summary of radical prostatectomy and eLND in high-risk localized disease).

- **Chapter 10 “Treatment: definitive radiotherapy”**
  The literature has been updated, as well as the findings in section 10.10 (Guidelines for definitive radiotherapy). The text has been completely restructured, in particular in sections 10.3.2 (Neoadjuvant or adjuvant hormone therapy plus radiotherapy), 10.3.2.3 (high-risk group), 10.3.4 (The benefits of lymph-node irradiation in the prostate), 10.3.4.2 (Very high-risk PCa) and 10.7.1 (Immediate [adjuvant] postoperative external irradiation after radical prostatectomy).

- **Chapter 12 “Hormonal therapy; rationale and available drugs”**
  The literature has been updated. The chapter has been completely restructured and a section of the text was moved into a separate chapter (Chapter 15 “Metastatic prostate cancer – Hormonal therapy”), to facilitate consultation.

- **Chapter 13 “Metastatic Prostate Cancer – Hormonal therapy”**
  The literature has been updated and the text was restructured. In particular information has been added, in sections 13.1 (Prognostic factors), and 13.4 (Indications for hormonal therapy). Also section 13.4 (indications for hormonal therapy) was revised.

- **Chapter 15 “Quality of life of patients with localised prostate cancer”**
  The literature has been updated.

- **Chapter 18 “Treatment of biochemical failure after treatment with curative intent”**
  The literature has been updated and the text has been restructured.

- **Chapter 19 “Treatment of biochemical failure after curative intent”**
  The literature has been updated. Additional information on imaging modalities has been added, most notably in the summary at the end of section 19.4.1 (Diagnostic procedures for PSA relapse following radical prostatectomy). New data has been included in sections 19.4.2 (Diagnostic studies for PSA relapse following radiation therapy), 19.5.1 (Radiotherapy for PSA-only recurrence after radical prostatectomy) and on new techniques in section 19.6.1 (Salvage radical prostatectomy).

- **Chapter 20 “Castration-resistant prostate cancer (CRPC)”**
  The literature has been updated resulting in minor changes to the recommendations. The text has been completely restructured and a new algorithm for PSA progression following initial hormonal therapy was added in section 20.5 (Secondary hormonal therapy). New information was included in
sections 20.8 (Novel hormonal drugs targeting the endocrine pathways), 20.9 (Non-hormonal therapy), as well as in section 20.11, resulting in expanding the recommendations for salvage treatment after Docetaxel. The summary of treatment recommendations (section 20.13) was subjected to a minor revision.

New topics included in this 2012 print
- Quality of life of patients with localised prostate cancer
- Chapter 16, A section has been added on salvage high-intensity focused ultrasound (HIFU)
- Chapter 17, Section 17.10.4 RANK ligand inhibitors

1.5 Potential conflict of interest statement
The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

1.6 References

2. BACKGROUND
Cancer of the prostate (PCa) is now recognised as one of the most important medical problems facing the male population. In Europe, PCa is the most common solid neoplasm, with an incidence rate of 214 cases per 1000 men, outnumbering lung and colorectal cancer (1). Furthermore, PCa is currently the second most common cause of cancer death in men (2). In addition, since 1985, there has been a slight increase in most countries in the number of deaths from PCa, even in countries or regions where PCa is not common (3).

Prostate cancer affects elderly men more often than young men. It is therefore a bigger health concern in developed countries with their greater proportion of elderly men. Thus, about 15% of male cancers are PCa in developed countries compared to 4% of male cancers in developing countries (4). It is worth mentioning that there are large regional differences in incidence rates of PCa. For example, in Sweden, where there is a long life expectancy and mortality from smoking-related diseases is relatively modest, PCa is the most common malignancy in males, accounting for 37% of all new cases of cancer in 2004 (5).

### 3. CLASSIFICATION

The 2009 TNM (Tumour Node Metastasis) classification for PCa is shown in Table 3 (1).

**Table 3: Tumour Node Metastasis (TNM) classification of PCa**

<table>
<thead>
<tr>
<th>T - Primary tumour</th>
<th>T0</th>
<th>T1a</th>
<th>T1b</th>
<th>T1c</th>
</tr>
</thead>
<tbody>
<tr>
<td>Primary tumour cannot be assessed</td>
<td>No evidence of primary tumour</td>
<td>Clinically inapparent tumour not palpable or visible by imaging</td>
<td>Tumour incidental histological finding in 5% or less of tissue resected</td>
<td>Tumour incidental histological finding in more than 5% of tissue resected</td>
</tr>
<tr>
<td>T2a</td>
<td>Tumour involves one half of one lobe or less</td>
<td>T2b</td>
<td>Tumour involves more than half of one lobe, but not both lobes</td>
<td>Tumour involves both lobes</td>
</tr>
<tr>
<td>T3a</td>
<td>Extracapsular extension (unilateral or bilateral) including microscopic bladder neck involvement</td>
<td>T3b</td>
<td>Tumour invades seminal vesicle(s)</td>
<td></td>
</tr>
<tr>
<td>T4</td>
<td>Tumour is fixed or invades adjacent structures other than seminal vesicles: external sphincter, rectum, levator muscles, and/or pelvic wall</td>

<tr>
<td>M1b</td>
<td>Bone(s)</td>
<td></td>
</tr>
<tr>
<td>M1c</td>
<td>Other site(s)</td>
<td></td>
</tr>
</tbody>
</table>

---

1. Tumour found in one or both lobes by needle biopsy, but not palpable or visible by imaging, is classified as T1c.
2. Invasion into the prostatic apex, or into (but not beyond) the prostate capsule, is not classified as pT3, but as pT2.
3. Metastasis no larger than 0.2 cm can be designated pN1 mi.
4. When more than one site of metastasis is present, the most advanced category should be used.
### Prognostic grouping

<td>N1</td>
<td>M0 Any PSA</td>
<td>Any Gleason</td>
</tr>
<tr>
<td></td>
<td>Any T</td>
<td>Any N</td>
<td>M1 Any PSA</td>
<td>Any Gleason</td>
</tr>
</tbody>
</table>

**Note:** When either PSA or Gleason is not available, grouping should be determined by cT category and whichever of either PSA or Gleason is available. When neither is available, and prognostic grouping is not possible, use stage grouping.

### 3.1 Gleason score

The ISUP 2005 Gleason score is the current standard for grading adenocarcinoma of the prostate on core biopsy and operative specimens (2). The Gleason score is the sum of the two most common patterns (grades 1-5) of tumour growth found. The Gleason score ranges between 2 and 10, with 2 being the least aggressive and 10 the most aggressive. In needle biopsies, the worst grade should always be incorporated in the Gleason score, even if comprising < 5% of the cancer (2).

### 3.2 References

### 4. RISK FACTORS

The factors that determine the risk of developing clinical PCa are not well known, although a few have been identified. There are three well-established risk factors for PCa:

- increasing age;
- ethnic origin;
- heredity.

If one first-line relative has PCa, the risk is at least doubled. If two or more first-line relatives are affected, the risk increases by 5-11-fold (1,2). A small subpopulation of individuals with PCa (about 9%) has true hereditary PCa. This is defined as three or more affected relatives, or at least two relatives who have developed early-onset disease, i.e. before age 55 (2). Patients with hereditary PCa usually have an onset 6-7 years prior to spontaneous cases, but do not differ in other ways (2).

The frequency of autopsy-detected cancers is roughly the same in different parts of the world (3). This finding is in sharp contrast to the incidence of clinical PCa, which differs widely between different geographical areas, being high in the USA and Northern Europe and low in Southeast Asia (4). However, if Japanese men move from Japan to Hawaii, their risk of PCa increases. If they move to California their risk increases even more, approaching that of American men (4) (LE: 2).

These findings indicate that exogenous factors affect the risk of progression from so-called latent PCa...
to clinical PCa. Factors such as food consumption, pattern of sexual behaviour, alcohol consumption, exposure to ultraviolet radiation, chronic inflammation (5,6) and occupational exposure have all been discussed as being aetiologically important (6). Prostate cancer may be an ideal candidate for exogenous preventive measures, such as dietary and pharmacological prevention, due to some specific features: high prevalence, long latency, endocrine dependency, availability of serum markers (PSA), and histological precursor lesions (atypical small acinar proliferation [ASAP] or prostatic intraepithelial neoplasia [PIN]) (5). Dietary/nutritional factors that may influence disease development include total energy intake (as reflected by body mass index), dietary fat, cooked meat, micronutrients and vitamins (carotenoids, retinoids, vitamins C, D, and E), fruit and vegetable intake, minerals (calcium, selenium), and phyto-estrogens (isoflavonoids, flavonoids, lignans), or statins and/or cholesterol intake. Since most studies reported to date are case-control analyses, there remain more questions than evidence-based data available to answer them. Several ongoing large randomised trials are trying to clarify the role of such risk factors and the potential for successful prostate cancer prevention (7).

Several studies posed that metabolic syndrome may be involved in the pathogenesis and progression of prostate diseases such as benign prostatic hyperplasia (BPH) and PCa (8,9). Even though the underlying causes are still unclear, investigators established an association between an increase of insulin resistance and hyperinsulinemia, responsible for insulin-like growth factor 1 (IGF-1) production in the liver. IGF-1 is a potent mitogenic factor and apoptosis inhibitor that has been linked to PCa risk (10).

In summary, hereditary factors are important in determining the risk of developing clinical PCa, while exogenous factors may have an important impact on this risk. The key question is whether there is enough evidence to recommend lifestyle changes (lowered intake of animal fat and increased intake of fruit, cereals, and vegetables) in order to decrease the risk (11). There is some evidence to support such a recommendation and this information can be given to male relatives of PCa patients who ask about the impact of diet (LE: 2-3).

4.1 References

5. SCREENING AND EARLY DETECTION

Population or mass screening is defined as the examination of asymptomatic men (at risk). It usually takes place as part of a trial or study and is initiated by the screener. In contrast, early detection or opportunistic screening comprises individual case findings, which are initiated by the person being screened (patient) and/or his physician. The primary endpoint of both types of screening has two aspects:

1. Reduction in mortality from PCa. The goal is not to detect more carcinomas, nor is survival the endpoint because survival is strongly influenced by lead-time from diagnosis.
2. The quality of life is important as expressed by quality-of-life adjusted gain in life years (QUALYs).

Prostate cancer mortality trends range widely from country to country in the industrialised world (1). Decreased mortality rates due to PCa have occurred in the USA, Austria, UK, and France, while in Sweden the 5-year survival rate has increased from 1960 to 1988, probably due to increased diagnostic activity and greater detection of non-lethal tumours (2). However, this trend has not been confirmed in a similar study from the Netherlands (3). The reduced mortality seen recently in the USA is often attributed to the widely adopted aggressive screening policy, but there is still no absolute proof that prostate-specific antigen (PSA) screening reduces mortality due to PCa (4) (LE: 2).

A non-randomised screening project in Tyrol (Austria) may support the hypothesis that screening can be effective in reducing mortality from PCa. An early detection programme and free treatment have been used to explain the 33% decrease in the PCa mortality rate seen in Tyrol compared to the rest of Austria (5) (LE: 2b). In addition, a Canadian study has claimed lower mortality rates in men randomised to active PCa screening (6), though these results have been challenged (7). Positive findings attributed to screening have also been contradicted by a comparative study between the US city of Seattle area (highly screened population) and the US state of Connecticut (seldom screened population) (8). The study found no difference in the reduction in the rate of PCa mortality (LE: 2b), even allowing for the very great diversity in PSA testing and treatment.

In 2009, the long awaited results of two prospective, randomised trials were published. The Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial randomly assigned 76,693 men at 10 US centres to receive either annual screening with PSA and DRE, or standard care as the control. After 7 years’ follow-up, the incidence of PCa per 10,000 person-years was 116 (2,820 cancers) in the screening group and 95 (2,322 cancers) in the control group (rate ratio, 1.22) (9). The incidence of death per 10,000 person-years was 2.0 (50 deaths) in the screened group and 1.7 (44 deaths) in the control group (rate ratio, 1.13). The data at 10 years were 67% complete and consistent with these overall findings. The PLCO project team concluded that PCa-related mortality was very low and not significantly different between the two study groups (LE: 1b).

The European Randomized Study of Screening for Prostate Cancer (ERSPC) included a total of 162,243 men from seven countries aged between 55 and 69 years. The men were randomly assigned to a group offered PSA screening at an average of once every 4 years or to an unscreened control group. During a median follow-up of 9 years, the cumulative incidence of PCa was 8.2% in the screened group and 4.8% in the control group (10). The rate ratio for death from PCa was 0.80 in the screened group compared with the control group. The absolute risk difference was 0.71 deaths per 1,000 men. This means that 1,410 men would need to be screened and 48 additional cases of PCa would need to be treated to prevent one death from PCa. The ERSPC investigators concluded that PSA-based screening reduced the rate of death from PCa by 20%, but was associated with a high risk of over-diagnosis (LE: 1b).

Both trials have received considerable attention and comments. In the PLCO trial, the rate of compliance in the screening arm was 85% for PSA testing and 86% for DRE. However, the rate of contamination in the control arm was as high as 40% in the first year and increased to 52% in the sixth year for PSA testing and ranged from 41% to 46% for DRE. Furthermore, biopsy compliance was only 40-52% versus 86% in the ERSPC. Thus, the PLCO trial will probably never be able to answer whether or not screening can influence PCa mortality.

In an update of the Gothenburg section of the ERSPC trial, which includes 20,000 men, the authors reported a reduction in PCa mortality of 50% after a median follow-up of 14 years. However, this finding was accompanied by a substantial risk of over-diagnosis (11).

In the complete ERSCP trial, the real benefit will only be evident after 10-15 years of follow-up, especially once the 41% reduction of metastasis in the screening arm has had an impact. A longer follow-up may reduce the number needed to screen and to treat (12).

Based on the results of these two large, randomised trials, most if not all of the major urological societies conclude that at present widespread mass screening for PCa is not appropriate. Rather, early detection (opportunistic screening) should be offered to the well-informed man (see also Chapter 6, Diagnosis). Two key questions remain open:

- At what age should early detection start?
- What is the screening interval for PSA and DRE?
A baseline PSA determination at age 40 years has been suggested, upon which the subsequent screening interval may then be based (13) (GR: B). A screening interval of 8 years might be enough in men with initial PSA levels < 1 ng/mL (14). Further, PSA testing in men older than 75 years is not recommended because its early detection would not have any clinical impact (15).

5.1 References

6. **DIAGNOSIS**

The main diagnostic tools to obtain evidence of PCa include DRE, serum concentration of PSA, and transrectal ultrasonography (TRUS). Its definite diagnosis depends on the histopathologic verification of adenocarcinoma in prostate biopsy cores or operative specimens.

6.1 **Digital rectal examination (DRE)**

Most prostate cancers are located in the peripheral zone of the prostate and may be detected by DRE when the volume is about 0.2 mL or larger. In about 18% of all patients, PCa is detected by a suspect DRE alone, irrespective of the PSA level (1) (LE: 2a). A suspect DRE in patients with a PSA level of up to 2 ng/mL has a positive predictive value of 5-30% (2) (LE: 2a). A suspect DRE is a strong indication for prostate biopsy as it is predictive for more aggressive (Gleason score ≥ 7) prostate cancer (3,4).

6.2 **Prostate-specific antigen (PSA)**

The measurement of PSA level has revolutionised the diagnosis of PCa (5). PSA is a kallikrein-like serine protease produced almost exclusively by the epithelial cells of the prostate. For practical purposes, it is organ-specific but not cancer-specific. Thus, serum levels may be elevated in the presence of benign prostatic hypertrophy (BPH), prostatitis and other non-malignant conditions. The level of PSA as an independent variable is a better predictor of cancer than suspicious findings on DRE or TRUS (6).

There are many different commercial test kits for measuring PSA, but no commonly agreed international standard exists (7). The level of PSA is a continuous parameter: the higher the value, the more likely is the existence of PCa. The finding that many men may harbour PCa, despite low levels of serum PSA, has been underscored by recent results from a US prevention study (8) (LE: 2a). Table 4 gives the rate of PCa in relation to serum PSA for 2,950 men in the placebo-arm and with PSA values ≤ 4 ng/mL.

The findings in Table 4 clearly demonstrate the occurrence of aggressive PCa even at very low PSA levels, precluding an optimal PSA threshold value for detecting non-palpable, but clinically significant, PCa (LE: 3). Use of nomograms may help reducing the number of unnecessary prostate biopsies (9).

Several modifications of serum PSA value have been described, which may improve the specificity of PSA in the early detection of PCa. They include: PSA density, PSA density of the transition zone, age-specific reference ranges, and PSA molecular forms. However, these derivatives and PSA isoforms (cPSA [complex PSA], proPSA [precursor isoforms of PSA], BPSA [benign PSA], iPSA [intact PSA]) have limited usefulness in the routine clinical setting and have therefore not been considered for inclusion in these guidelines.

6.2.1 **Free/total PSA ratio (f/t PSA)**

The free/total PSA ratio (f/t PSA) is the concept most extensively investigated and most widely used in clinical practice to discriminate BPH from PCa. The ratio is used to stratify the risk of PCa for men who have total PSA levels between 4 and 10 ng/mL and a negative DRE. In a prospective multicentre trial, PCa was found on biopsy in 56% of men with f/t PSA < 0.10, but in only 8% of men with f/t PSA > 0.25 (10) (LE: 2a). Nevertheless, the concept must be used with caution as several pre-analytical and clinical factors may influence the f/t PSA, e.g. instability of free PSA, variable assay characteristics and very large prostate size (11). For example, free PSA is unstable at both 4°C and at room temperature. In addition, assay characteristics may vary, and concomitant BPH in large prostates may result in a dilution effect (11). Furthermore, f/t PSA is of no clinical use in total serum PSA values > 10 ng/mL or during follow-up of patients with known PCa.

*Acknowledgment: Section 6.4 is partly based on the Guidelines of the AUO Study Group Urologic Oncology of the Austrian Society of Urologists and Andrologists (W. Höltl, W. Loidl, M. Rauchenwald, M. Müller, M. Klimpfinger, A. Schratter-Sehn, C. Brössner).*
6.2.2 **PSA velocity (PSAV), PSA doubling time (PSADT)**

There are two methods of measuring PSA over time:

- **PSAV**, which is defined as an absolute annual increase in serum PSA (ng/mL/year) (12) (LE: 1b);
- **PSADT**, which measures the exponential increase of serum PSA over time, reflecting a relative change (13).

These two concepts may have a prognostic role in patients with treated PCa (14), but they have limited use in the diagnosis of PCa because of background noise (total volume of prostate, BPH), the variations in interval between PSA determinations, and acceleration/deceleration of PSAV and PSADT over time. Prospective studies have shown that these measurements do not provide additional information compared to PSA alone (15-18).

6.2.3 **PCA3 marker**

An increasingly studied new biomarker is PCA3, detectable in urine sediments obtained after three strokes of prostatic massage during digital rectal examination. The costly Progensa urine test for PCA3 is now commercially available. The amount of the prostate-specific non-coding mRNA marker, PCA3 normalised against PSA mRNA (urine sediment) gives a PCA3 score. The PCA3 score is superior to PSA total, and percent free PSA in detection of PCa in men with elevated PSA as it shows slight but significant increases in the AUC for positive biopsies (19-22). The PCA3 score may be used together with PSA and other clinical risk factors in a nomogram or other risk stratification tools to make a decision with regard to first or repeat biopsy (23). The PCA3 score increases with prostate cancer volume, but there is conflicting data about whether the PCA3 score independently predicts the Gleason score and its use as a monitoring tool in active surveillance has not been confirmed (23). The main current indication of the PCA3 urine test may be to determine whether a man needs a repeat biopsy after an initially negative biopsy outcome, but its cost-effectiveness remains to be shown.

6.3 **Transrectal ultrasonography (TRUS)**

The classic picture of a hypoechoic area in the peripheral zone of the prostate will not always be seen. Gray-scale TRUS does not detect areas of PCa with adequate reliability (24). It is therefore not useful to replace systematic with targeted biopsies of suspect areas. However, additional biopsies of suspect areas may be useful.

6.4 **Prostate biopsy**

6.4.1 **Baseline biopsy**

The need for prostate biopsies should be determined on the basis of the PSA level and/or a suspicious DRE. The patient's biological age, potential co-morbidities (ASA Index and Charlson Comorbidity Index), and the therapeutic consequences should also be considered (25). Risk stratification is becoming an important tool to reduce unnecessary prostate biopsies (25).

The first elevated PSA level should not prompt an immediate biopsy. The PSA level should be verified after a few weeks by the same assay under standardised conditions (i.e. no ejaculation and no manipulations, such as catheterisation, cystoscopy or TUR, and no urinary tract infections) in the same diagnostic laboratory, using the same methods (26,27) (LE: 2a).

It is now considered the standard of care to perform prostate biopsies guided by ultrasound. Although a transrectal approach is used for most prostate biopsies, some urologists prefer to use a perineal approach. The cancer detection rates of perineal prostate biopsies are comparable to those obtained for transrectal biopsies (28,29) (LE: 1b).

The ultrasound-guided perineal approach is a useful alternative in special situations, e.g. after rectal amputation.

6.4.2 **Repeat biopsy**

The indications for a repeat biopsy are:

- rising and/or persistently elevated PSA;
- suspicious DRE (30);
- atypical small acinar proliferation (ASAP);
- extensive (multiple biopsy sites) prostatic intraepithelial neoplasia (PIN) (31).

High-grade PIN as an isolated finding is no longer considered an indication for repeat biopsy (32) (LE: 2a). A repeat biopsy should therefore be prompted by other clinical features, such as DRE findings and PSA level. If PIN is extensive (i.e. in multiple biopsy sites), this could be a reason for early repeat biopsy, because the risk of subsequent PCa is slightly increased. If clinical suspicion for PCa persists in spite of negative prostate biopsies, magnetic resonance imaging (MRI) may be used to investigate the possibility of an anterior located...
PCa, followed by TRUS or MRI-guided biopsies of the suspicious area (33).

6.4.3 **Saturation biopsy**
The incidence of PCa detected by saturation repeat biopsy (> 20 cores) is between 30% and 43% and depends on the number of cores sampled during earlier biopsies (34) (LE: 2a). In special situations, saturation biopsy may be performed with the transperineal technique. This will detect an additional 38% of PCa. The high rate of urinary retention (10%) is a drawback (35) (LE: 2b).

6.4.4 **Sampling sites and number of cores**
On baseline biopsies, the sample sites should be as far posterior and lateral as possible in the peripheral gland. Additional cores should be obtained from suspect areas by DRE/TRUS. These should be chosen on an individual basis.

Sextant biopsy is no longer considered adequate. At a glandular volume of 30-40 mL, at least eight cores should be sampled. The British Prostate Testing for Cancer and Treatment Study has recommended 10 core biopsies (36) (LE: 2a). More than 12 cores are not significantly more conclusive (37) (LE: 1a).

6.4.5 **Diagnostic transurethral resection of the prostate (TURP)**
The use of diagnostic TURP instead of repeat biopsies is a poor tool for cancer detection (38) (LE: 2a).

6.4.6 **Seminal vesicle biopsy**
Indications for seminal vesicle (staging) biopsies are poorly defined. At PSA levels > 15-20 ng/mL, the odds of tumour involvement are 20-25% (39) (LE: 2a), but a biopsy is only useful if the outcome will have a decisive impact on treatment, i.e. if the biopsy result rules out radical removal for tumour involvement or radiotherapy with intent to cure.

6.4.7 **Transition zone biopsy**
Transition zone (TZ) sampling during baseline biopsies provides a very low detection rate and TZ sampling should therefore be confined to repeat biopsies (40) (LE: 1b).

6.4.8 **Antibiotics prior to biopsy**
Oral or intravenous antibiotics are state-of-the-art treatment. Optimal dosing and treatment time vary. Quinolones are the drugs of choice, with ciprofloxacin superior to ofloxacin (41) (LE: 1b), but in the last few years increased resistance to quinolones has been reported (42) associated with a rise in severe infectious complications after biopsy (43).

6.4.9 **Local anaesthesia prior to biopsy**
Ultrasound-guided peri-prostatic block is state-of-the-art (44) (LE: 1b). It does not make any difference whether the depot is apical or basal. Intrarectal instillation of a local anaesthetic is clearly inferior to peri-prostatic infiltration (45) (LE: 1b).

6.4.10 **Fine-needle aspiration biopsy**
Fine-needle aspiration biopsy is no longer state-of-the-art.

6.4.11 **Complications**
Complications include macrohaematuria and haematospermia (Table 5) (46). Severe post-procedural infections were initially reported in < 1% of cases, but this rate has increased in the last few years as a consequence of the evolution of antibiotic resistance strains with more post-biopsy hospitalisations for infectious complications while the rate of non-infectious complications has remained stable (43).

Low-dose aspirin is no longer an absolute contraindication (47) (LE: 1b).

| Table 5: Percentage given per biopsy session, irrespective of the number of cores* |
|----------------------------------------|-------------------------------|
| Complication                          | % of biopsies                 |

6.5 Pathology of prostate needle biopsies

6.5.1 Grossing and processing
Prostate core biopsies taken from different sites are usually sent to the pathology laboratory in separate vials and should be processed in separate cassettes. Before processing, number of cores per vial and length of each core should be recorded. There is a significant correlation between the length of prostate biopsy tissue on the histological slide and the detection rate of PCa (48). To achieve optimal flattening and alignment of individual cores, one should embed a maximum of three cores per cassette and use sponges or paper to keep the cores stretched and flat (49,50). To optimise the detection of small lesions, blocks should be cut at three levels (40). It is helpful routinely to mount intervening tissue sections in case additional immunostaining is needed.

6.5.2 Microscopy and reporting
Diagnosis of prostate cancer is based on histological examination. Ancillary staining techniques (e.g. basal cell staining) and additional (deeper) sections should be considered if a suspect lesion is identified (51-53). Diagnostic uncertainty in biopsies may often be resolved by intradepartmental consultation or a second opinion from an external institution (51). Table 6 lists recommended concise terminology to report prostate biopsies (50).

Table 6: Recommended diagnostic terms to report prostate biopsy findings*

*From Van der Kwast, 2003 (49).

PIN = prostatic intra-epithelial neoplasia.

For each biopsy site, the proportion of biopsies positive for carcinoma and the ISUP 2005 Gleason score should be reported (54). A recent study has demonstrated the improved concordance of pattern and change of prognostic groups for the modified Gleason grading (55). According to current international convention, the (modified) Gleason score of cancers detected in prostate biopsy consists of the Gleason grade of the dominant (most extensive) carcinoma component plus the highest grade, irrespective of its extent (no 5% rule). When the carcinoma largely consists of grade 4/5 carcinoma, identification of a small portion (< 5% of the carcinoma) of Gleason grade 2 or 3 glands should be ignored. A diagnosis of Gleason score 4, or lower, should not be given on prostate biopsies (54). The presence of intraductal carcinoma and extraprostatic extension should be reported. In addition to a report of the carcinoma features for each biopsy site, an overall Gleason score based on findings in the individual biopsies is commonly provided.

The proportion (%) or length (mm) of tumour involvement per biopsy core correlates with tumour volume, extraprostatic extension, and prognosis after prostatectomy (56-58), and an extent of > 5 mm or > 50% of adenocarcinoma in a single core is used as a cut-off triggering immediate treatment versus active surveillance in patients with Gleason score 6 carcinoma. For these reasons a measure of the extent of cancer involvement (mm or %) should be provided for each core. Length of carcinoma and percentage of carcinoma involvement of the biopsy have equal prognostic impact (59).

The extent of a single, small focus of adenocarcinoma, which is located in only one of the biopsies, should be clearly stated (e.g. < 1 mm or < 1%), as this might be an indication for further diagnostic work-
up before selecting therapy as this finding is associated with an increased risk of vanishing cancer (60-62). A prostate biopsy that does not contain glandular prostate tissue should be reported as inadequate for diagnostics, except for staging biopsies.

6.6 Pathohistology of radical prostatectomy (RP) specimens

6.6.1 Processing of the RP specimen

The histopathological examination of RP specimens aims to provide information about the actual pathological stage, grade, and surgical margin status of the prostate cancer. The weight and dimensions of the specimen are recorded before embedding it for histological processing. It is generally recommended that RP specimens are totally embedded to enable the best assessment of location, multifocality, and heterogeneity of the cancer.

However, for cost-effectiveness, partial embedding using a standard method may also be considered, particularly for large prostates (> 60 g). The most acceptable method includes the complete embedding of the posterior (dorsal) part of the prostate in addition to a single mid-anterior left and right section. Compared to total embedding, this method of partial embedding permitted detection of 98% of prostate cancers with a Gleason score \( \geq 7 \) and accurate staging in 96% of cases (63).

Upon receipt in the histopathology laboratory, the entire RP specimen is inked in order to appreciate the surgical margin status. The specimen is fixed by immersion in buffered formalin for a few days, preferably prior to incision of the sample, as incision causes distortion of the tissue. Fixation can be enhanced by injecting formalin using 21-gauge syringes, which provides a more homogeneous fixation and sectioning after 24 hours (64). After fixation, the apex is removed and cut with (para)sagittal or radial sections; the shave method is not recommended (65). Separate removal and sagittal sectioning of the bladder neck is optional. The remainder of the RP specimen is generally cut in transverse sections at 3-4 mm steps, perpendicularly to the posterior surface. The resultant tissue slices can be embedded and processed either as whole-mounts or after quadrant sectioning. Whole-mount processing provides better topographic visualisation of the carcinoma and faster histopathological examination. However, it is a more time-consuming and more expensive technique that requires specialised equipment and personnel. Although whole-mount sectioning may be necessary for research, its advantages do not outweigh its disadvantages for routine sectioning.

6.6.1.1 Recommendations for processing a prostatectomy specimen

<table>

6.6.2 RP specimen report

The pathology report provides essential information on the prognostic characteristics relevant for making clinical decisions (Table 7). As a result of the complex information provided on each RP specimen, the use of synoptic-(like) or checklist reporting is recommended (Table 8). Synoptic reporting of surgical specimens results in more transparent and complete pathology reporting (66).
Table 7: Information provided by the pathology report

| Typing (> 95% of PCa represents conventional (acinar) adenocarcinoma) |
|-------------------|------------------|
| Grading according to the Gleason score |
| (Sub)staging and surgical margin status of the tumour |
| If appropriate, location and extent of extraprostatic extension, presence of bladder neck invasion, laterality of extraprostatic extension or seminal vesicle invasion, location and extent of positive surgical margins |
| Additional information may be provided on multifocality, diameter of the dominant tumour and zonal location (transition zone, peripheral zone, anterior horn) of the dominant tumour |

6.6.2.1 Gleason score
Grading of conventional prostatic adenocarcinoma using the (modified) Gleason score system (54) is the single strongest prognostic factor for clinical behaviour and treatment response. The Gleason score is therefore one of the parameters incorporated in nomograms that predict the risk of recurrence after prostatectomy (67).

6.6.2.2 Interpreting the Gleason score
The Gleason score is the sum of the most dominant and second most dominant (in terms of volume) Gleason grade. If only one grade is present, the primary grade is doubled. If a grade comprises ≤ 5% of the cancer volume, this grade is not incorporated in the Gleason score (5% rule). Both the primary and the secondary grade are reported in addition to the Gleason score (e.g. Gleason score 7 [4 + 3]). A global Gleason score is
given when there are multiple tumours, but a separate tumour focus with a higher Gleason score should also be mentioned. A tertiary Gleason grade 4 or 5, particularly if exceeding 5% of the prostate cancer volume, is an unfavourable prognostic indicator for biochemical recurrence. The presence of the tertiary grade and its approximate proportion of the cancer volume should also be reported (68), in addition to the Gleason score.

6.6.2.3 Definition of extraprostatic extension

The TNM staging system of the International Union Against Cancer (UICC) is recommended for pathological staging of prostate carcinoma (65,69). Pathologic substaging of pT2 prostate cancer is optional, since it does not correlate with clinical T2 substage and it lacks prognostic significance (70).

Extraprostatic extension is the recommended term for the presence of tumour beyond the confines of the prostate. Extraprostatic extension is defined as carcinoma mixed with periprostatic adipose tissue, or bulging out beyond the contours of the prostate gland, e.g. at the neurovascular bundle or the anterior prostate. Bladder neck invasion is also considered to be an extraprostatic extension.

It is useful to report not only the location, but also the extent of extraprostatic extension because extension is related to the risk of recurrence. There are no well-established and internationally accepted definitions of the terms ‘focal’ and ‘non-focal’ or ‘extensive extraprostatic extension’. Some authors describe focal as ‘a few glands’ (71) or extension < 1 high-power field (72), whereas others measure the depth of extent in mm (73). Currently, it is considered clinically useful to report the extent of extraprostatic extension (e.g. less or more than 1 high-power field or 1 mm) (74).

At the apex of the prostate gland, tumour mixed with skeletal muscle does not constitute extraprostatic extension. In the bladder neck, microscopic invasion of small fibres of smooth muscle is not equated to (gross) bladder wall invasion, because it does not carry independent prognostic significance for PSA recurrence (75,76) and should be recorded as extraprostatic extension (pT3a). A positive margin at the bladder neck should be reported as an extraprostatic extension (pT3a) with positive margin and not as pT4 disease. Stage pT4 can only be assigned when the tumour invades the muscle wall of the bladder as determined by the urologist (77).

6.6.3 Prostate cancer volume

The independent prognostic value of the volume of PCa in RP specimens has not been established (72,78-81). Nevertheless, a PCa volume cut-off of 0.5 mL continues to be an important parameter to distinguish insignificant from clinically relevant cancer (78). Continued improvement in radioimaging of the prostate gland has allowed more accurate measurement of cancer volume before surgery. Therefore, it may be recommended to assess the greatest dimension of the dominant tumour nodule, if identified, or to provide a rough estimate of the percentage of cancer tissue in the prostate.

6.6.4 Surgical margin status

Surgical margin status is an independent risk factor for biochemical recurrence. Margin status is positive if tumour cells are in touch with the ink on the surface of the specimen. Margin status is negative if tumour cells are very close to the inked surface of the margin (79) or when they are at the surface of the tissue lacking any ink.

If the tissue has severe crush artifacts (usually at the apex), it may not be possible to assign a surgical margin status (82). Surgical margin status is independent of the pathological stage and a positive margin is not evidence of extraprostatic extension (83). There is insufficient evidence to prove a relationship between the extent of positive margin and the risk of recurrence (72). However, some indication must be given of the multifocality and extent of margin positivity, such as the linear extent in millimetres, or number of blocks with positive margin involvement.

6.6.5 Other factors

According to the College of American Pathologists consensus statement (84), additional potential biomarkers have not been sufficiently studied to demonstrate their additional prognostic value and clinical usefulness outside the standard patient care setting (category III), including perineural invasion, neuroendocrine differentiation, microvessel density, nuclear roundness, chromatin texture, other karyometric factors, proliferation markers, prostate-specific antigen derivatives, and other factors (e.g. oncogenes, tumour suppressor genes, or apoptosis genes).

7. CLINICAL STAGING

The primary extension assessment of prostate cancer (PCa) is usually made by DRE, PSA measurement, and bone scan, supplemented with computed tomography (CT) or MRI and chest X-ray in specific situations.

7.1 T-staging
The first level is the assessment of local tumour stage, where the distinction between intracapsular (T1-T2) and extraprostatic (T3-T4) disease has the most profound impact on treatment decisions. DRE often underestimates the tumour extension; a positive correlation between DRE and pathological tumour stage was found in fewer than 50% of cases (1). However, more extensive examinations for adequate T-staging are only recommended in selected cases when more precise staging directly affects the treatment decision, i.e. when curative treatment is an option.

Serum PSA levels increase with advancing stage. Nevertheless, when PSA level is measured in an individual patient, it appears to have a limited ability to predict the final pathological stage accurately. Due to the production of PSA by benign and malignant prostatic tissue, there is no direct relationship between serum PSA concentration and the clinical and pathological tumour stage (2). A combination of serum PSA level, Gleason score on prostate biopsy and clinical T-stage, however, has been proven to be more useful in predicting the final pathological stage than the individual parameters per se (3).

The ability of the molecular forms of PSA to predict T-stage is controversial and their routine measurement is not indicated (4,5). The most commonly used method for viewing the prostate is TRUS. However, only 60% of tumours are visible with TRUS, and the remainder are not recognised due to their isoechogenicity. In a large multi-institutional study, TRUS was no more accurate at predicting organ-confined disease than was DRE (6). These findings were supported by another large study, which showed that there was no meaningful superiority of TRUS over DRE (7). A combination of DRE and TRUS can detect T3a PCa more accurately than either method alone (8) (LE: 3).

Three-dimensional TRUS (3D-TRUS) claimed to have better staging accuracy than 2-D techniques (9). Several adjuncts to 3D greyscale TRUS have been investigated. A greater sensitivity for cancer detection has been achieved with the addition of power colour Doppler and contrast agents (10-12). Unfortunately, all TRUS techniques remain largely operator-dependent and are not able to differentiate between T2 and T3 tumours with sufficient accuracy to be recommended for routine use in staging.

Seminal vesicle invasion is predictive of local relapse and distant failure. Seminal vesicle biopsies may be used to increase the accuracy of pre-operative staging (13). This is not recommended as a first-line examination, but should be reserved for patients with a substantial risk of seminal vesicle invasion in whom a positive seminal vesicle biopsy would modify treatment decisions. Patients with a clinical stage greater than T2a and a serum PSA level of more than 10 ng/mL could be candidates for seminal vesicle biopsies (14,15). Patients with any of the basal biopsies positive for cancer are more likely to have positive seminal vesicle biopsies (16).

Of the prostate needle biopsy parameters examined, the percentage of tissue with cancer was the strongest predictor for positive surgical margins, seminal vesicle invasion and non-organ-confined disease (17). An increased number of biopsies involved with tumour independently predicts extraprostatic extension, margin involvement and lymph node invasion (18).

In a multivariate analysis, the best risk predictors of extracapsular extension on one side were the overall average of positive biopsy cores being 15% or greater, and the average from three ipsilateral biopsies being 15% or greater. When used in combination, these two factors yielded a model with a positive predictive value of 37%, and a negative predictive value of 95%. The high negative predictive value of the side-specific model identifies patients who are good candidates for nerve-sparing surgery (19). Furthermore, it may be useful to correlate the biopsy Gleason score with the final pathological stage: about 70% of patients have localised disease when the biopsy Gleason score is ≤ 6 (20).

It has been shown that transperineal three-dimensional prostate mapping biopsy (3D-PMB) provides more accurate determination of the extent and location of tumour compared to ultrasound guided 10-12 core biopsy, with Gleason score upgrading in 27.2% and up-staging in 45.6% of cases (21). The technique improves the differentiation between clinically significant cancers and low risk disease. Unlike transrectal saturation biopsy, 3D-PMB has acceptable morbidity.

Both CT and MRI are now of a high technical standard, but neither modality is sufficiently reliable to make their use mandatory in the assessment of local tumour invasion (22,23). Endorectal MRI (e-MRI) may allow for more accurate local staging by complementing the existing clinical variables by improvements in spatial characterisation of the prostatic zonal anatomy and molecular changes (24). Image quality and localisation improves significantly with e-MRI compared with external coil MRI (25). When compared with DRE and TRUS
prostate biopsy findings, e-MRI contributes significant incremental value for local PCa staging (26), particularly in the pre-operative identification of extraprostatic extension (EPE) and seminal vesicle invasion (SVI) when interpreted by dedicated genitourinary radiologists (27,28).

Endorectal MRI could impact on the decision to preserve or resect the neurovascular bundle (NVB) at the time of radical surgery (27,29,30).

When assessed for the ability to predict organ-confined PCa, the contribution of e-MRI to staging nomograms was significant in all risk categories, but the greatest benefit was seen in the intermediate and high risk groups (31). The combination of dynamic contrast-enhanced MRI and T2-weighted MR imaging yields improved assessment of EPE and better results for PCa staging compared with either technique independently (32) (LE: 3).

MR spectroscopic imaging (MRSI) allows for the assessment of tumour metabolism by displaying the relative concentrations of citrate, choline, creatinine and polyamines. Differences in the concentrations of these chemical metabolites between normal and malignant prostate tissues allow for better tumour localisation within the peripheral zone, increasing the accuracy of EPE detection among less-experienced readers, and decreasing interobserver variability (33). Furthermore, correlations have been demonstrated between the metabolic signal pattern and a pathological Gleason score, suggesting the potential for a non-invasive assessment of PCa aggressiveness (34).

Despite the proposed accuracy and benefit of e-MRI and MRSI in PCa characterisation and localisation, e-MRI has several limitations that hamper its widespread application in PCa staging, e.g. difficulties in interpreting signal changes related to post-biopsy haemorrhage and inflammatory changes of the prostate, and the unquantifiable but significant inter- and intra-observer variability seen between both non-dedicated and dedicated radiologists that may lead to under- or overestimation of tumour presence and the local extent of disease (LE: 3). The overall accuracy of 11C-choline positron emission tomography (PET) in defining local tumour stage (pT2 and pT3a-4) has been reported to be around 70%. PET tends to understage PCa, and has a limited value for making treatment decisions in patients with clinically localised PCa, especially if a nerve-sparing procedure is being considered (35) (LE: 2b).

7.2 N-staging

N-staging should be performed only when the findings will directly influence a treatment decision. This is usually the case in patients for whom potentially curative treatments are planned. High PSA values, stages T2b-T3 disease, poor tumour differentiation and peri-neural tumour invasion have been associated with a higher risk of the presence of nodal metastases (3,36,37). The measurement of PSA level alone is unhelpful in predicting the presence of lymph node metastases for an individual patient.

The nomograms could be used to define a group of patients with a low risk of nodal metastasis, i.e. < 10% (38). In such cases, patients with a serum PSA level of less than 20 ng/mL, stage T2a or less, and a Gleason score of 6 may be spared N-staging procedures before potentially curative treatment (3).

The extent of the Gleason 4 pattern in sextant biopsies has also been used to define the risk of N1 disease. If any core had a predominant Gleason 4 pattern, or > three cores any Gleason 4 pattern, the risk of nodal metastases was found to be 20-45%. For the remaining patients, the risk was 2.5%, supporting the idea that nodal staging is unnecessary in selected patients (39).

In the current published literature, the results indicate that CT and MRI perform similarly in the detection of pelvic lymph node metastases, although CT seems to be slightly superior (40) (LE: 2a). In either case, the decision about whether nodal involvement is present rests solely on whether there is enlargement of the investigated lymph nodes. A threshold of 1 cm for the oval nodes, and 0.8 cm for the round nodes, has been recommended as the criteria for the diagnosis of lymph node metastases (41).

A fine-needle aspiration biopsy (FNAB) might provide a decisive answer in cases of positive imaging results. However, the lymph node can be difficult to reach because of the anatomical position. In addition, FNAB is not a highly sensitive staging procedure, and a false-negative rate of 40% has been reported (41).

High-resolution MRI with lymphotrophic ultra-small super-paramagnetic iron oxide particles (USPIO) was more recently suggested in the detection of small and otherwise occult lymph node metastases in patients with PCa (42,43).

In asymptomatic patients with newly diagnosed PCa and a serum PSA level of less than 20 ng/mL, the likelihood of positive findings on CT or MRI is approximately 1% (32). CT scanning may therefore be warranted in patients with a very high risk of harbouring lymph node metastases, as the specificity of a positive scan is high (93-96%). Radio-immunoscintigraphy and PET have been investigated in order to improve the diagnosis of metastatic disease to the lymph nodes. Both methods are still under investigation, and further evaluation is needed before they can be recommended for routine use in clinical practice, especially as negative results should be interpreted with caution (44).

The results obtained using 18F-choline PET/CT scans for initial N-staging were discouraging, especially in terms of inability to detect small metastases/micrometastases (< 5 mm) (45). Furthermore,
\(^{11}\text{C}\)-choline PET/CT has quite a low sensitivity for the detection of lymph node metastases, but performed better than clinical nomograms, with equal sensitivity and better specificity (46).

The gold standard for N-staging is operative lymphadenectomy, either by open or laparoscopic techniques. It is worth pointing out that recent studies with more extensive lymphadenectomy have shown that the obturator fossa is not always the primary site for metastatic deposits in the lymph nodes, and pelvic lymph node dissection that is limited to the obturator fossa will therefore miss about 50\% of lymph node metastases (47,48). When deciding on pelvic lymph node dissection, extended lymphadenectomy should be considered, despite its disadvantages: it requires surgical experience; it is time-consuming; and it often leads to more complications than the limited procedures. Furthermore, it may fail to identify lymph node metastases, however present, even outside the region of extended dissection (49).

The primary removal of the so-called sentinel lymph node (SLN), defined as the first lymph node that receives lymphatic drainage from PCa, has the main aim of reducing the eventual morbidity associated with an extended pelvic node dissection, while preserving maximal sensitivity for diagnosis of metastatic disease (50) (LE: 3) (see section 9.7 Treatment: radical prostatectomy, indication and extent of eLND).

7.3 M-staging

The axial skeleton is involved in 85\% of patients who die from PCa (51). The presence and extent of bone metastases accurately reflect the prognosis for an individual patient. Elevated skeletal alkaline phosphatase levels may indicate the presence of bony metastasis in 70\% of affected patients (52). Furthermore, the measurement of skeletal alkaline phosphatase and PSA at the same time increases clinical effectiveness to approximately 98\% (53). In a prospective study, multiple regression analysis showed the extent of bone disease to be the only variable influencing the serum levels of skeletal alkaline phosphatase and PSA. However, in contrast to serum PSA, skeletal alkaline phosphatase demonstrated a statistical correlation with the extent of bone disease (54).

Early detection of bone metastases will alert the clinician to the possible complications inherent in skeletal destruction. Bone scintigraphy remains the most sensitive method of assessing bone metastases, being superior to clinical evaluation, bone radiographs, serum alkaline phosphatase measurement and prostatic acid phosphatase (PAP) determination (55,56). Technetium diphosphonates are the optimum radiopharmaceuticals currently available because of their extremely high bone-to-soft tissue ratio (57).

Increased \(^{18}\text{F}\)-fluoride uptake in malignant bone lesions reflects the increase in regional blood flow and bone turnover that characterise these lesions.

Studies have shown that \(^{18}\text{F}\)-fluoride PET/CT is a highly sensitive and specific imaging modality for detection of bone metastases (58,59). However, no definitive results have been obtained and therefore no final recommendations can be made (60).

Besides bone, PCa may metastasise to any organ, but most commonly it affects distant lymph nodes, lung, liver, brain and skin. Clinical examination, chest X-ray, ultrasound, CT and MRI scans are appropriate methods of investigation, but only if symptoms suggest the possibility of soft-tissue metastasis.

The need for reliable serum markers to improve the pre-treatment staging of patients with PCa has long been recognised. At present, PSA is the marker of choice. A pre-treatment serum PSA level greater than 100 ng/mL has been found to be the single most important indicator of metastatic disease, with a positive predictive value of 100\% (61). Furthermore, it has helped to reduce the number of patients with newly diagnosed PCa who require a bone scan. Patients with a low serum PSA concentration have only rarely been found to harbour detectable skeletal metastases. The correlation between serum PSA and bone scintigraphy in patients with newly diagnosed untreated PCa has been further investigated (62). Results suggest that a staging bone scan may be superfluous if the serum PSA concentration is less than 20 ng/mL in asymptomatic patients with well or moderately differentiated (up to 7: 3+4) tumours. In contrast, in patients with poorly differentiated tumours and locally advanced disease, a staging bone scan should be obtained irrespective of the serum PSA value (63).

8. TREATMENT: DEFERRED TREATMENT (WATCHFUL WAITING/ACTIVE MONITORING)

8.1 Introduction
There is a great difference between the incidence of PCa and deaths from PCa. In 2007, in the USA, there were 240,890 new cases with only 33,720 deaths (1). Several autopsy studies of people dying from different causes have shown that while 60-70% of older men have histological PCa (2), a large proportion of these tumours will not progress. Prostate cancer is diagnosed in only 15-20% of men during their lifetime, with a 3% lifetime risk of death (3).

The incidence of small, localised, well-differentiated PCa is increasing, mainly as a result of prostate-specific antigen (PSA) screening and ‘multicore’ schemes of prostate biopsy. These data suggest that many men with localised PCa would not actually benefit from definitive treatment. With the aim of reducing the risk of overtreatment in this subgroup of patients, two conservative management strategies of ‘watchful waiting’ and ‘active surveillance’ have been proposed.
8.1.1 Definition
8.1.1.1 Watchful waiting (WW)
Watchful waiting is also known as ‘deferred treatment’ or ‘symptom-guided treatment’. This term was coined in the pre-PSA screening era (before 1990) and referred to the conservative management of PCa until the development of local or systemic progression. At this point, the patient would then be treated palliatively with transurethral resection of the prostate (TURP) or other procedures for urinary tract obstruction, and hormonal therapy or radiotherapy for the palliation of metastatic lesions.

8.1.1.2 Active surveillance (AS)
Active surveillance is also known as ‘active monitoring’. It is the new term for the conservative management of PCa. Introduced in the past decade, it includes an active decision not to treat the patient immediately. Instead, the patient is followed up under close surveillance and treated at pre-defined thresholds that classify progression (i.e. short PSA doubling time and deteriorating histopathological factors on repeat biopsy). The treatment options are intended to be curative.

8.2 Deferred treatment of localised PCa (stage T1-T2, Nx-N0, M0)
8.2.1 Watchful waiting
The rationale behind WW is the observation that PCa often progresses slowly, and is diagnosed in older men, in whom there is a high incidence of co-morbidity and related high competitive mortality (4). Watchful waiting can be considered as an option for treating patients with localised PCa and a limited life expectancy or for older patients with less aggressive cancers.

There have been several attempts to summarise the key papers dealing with deferred treatment in patients with presumed localised PCa (5-7). Most have presented the same results, as they analyse roughly the same series, but using somewhat different methodologies. The outcome studies in WW usually included patients, whose PSA readings were not always available and who had predominantly palpable lesions that would currently be defined as intermediate-risk tumours (8). The most recent study used data from the PSA era of the Surveillance, Epidemiology and End Results (SEER) database of the National Cancer Institute in the USA (9). These studies included patients with a follow-up of up to 25 years, for whom the endpoints are overall survival (OS) and disease-specific survival (DSS).

Several WW series show a very consistent DSS ratio at 10 years, ranging from 82-87% (5,10-14), and up to 80-95% if T1-T2 Gleason ≤ 7 (9). In three studies with data beyond 15 years, the DSS was 80%, 79% and 58%, respectively (11,13,14). Two of them reported a 20-year DSS of 57% and 32%, respectively (11,13).

Chodak et al. reported a pooled analysis of the original data from 828 patients treated by WW (5). The paper was based on patients from six non-randomised studies and described cancer-specific survival and metastasis-free survival after 5 and 10 years of follow-up (5) (LE: 2b).

Tumour grade is clearly significant, with very low survival rates for grade 3 tumours. Although the 10-year cancer-specific rate is equally good (87%) for grade 1 and 2 tumours, the latter have a significantly higher progression rate, with 42% of these patients developing metastases (Table 9).

The importance of tumour grade on survival after conservative management of PCa was also underlined in a large register study using the SEER database (9) (LE: 3). Patients with grade 1, 2 and 3 tumours had 10-year cancer-specific survival rates of 91%, 90% and 74%, respectively, correlating with data from the pooled analysis.

The paper by Chodak et al. also specifically described the outcome for stage T1a patients (5), with cancer-specific 10-year survival rates of 96% and 94%, respectively, for grade 1 and 2 tumours. The metastasis-free survival rate was 92% for patients with grade 1 tumours, but 78% for those with grade 2...
tumours, indicating a higher risk of progression in individuals with moderately differentiated tumours. This difference in progression rate correlates with other studies on stage T1a disease (15,16).

The impact of grade on the risk of tumour progression and ultimately death from PCa was also described in a paper by Albertsen et al. in the pre-PSA era (17). The study re-evaluated all biopsy specimens using the more widely accepted Gleason score, and showed that the risk of PCa death was very high in Gleason 7-10 tumours, intermediate in Gleason 6 tumours, but low in Gleason 2-5 cancers (Table 10) (18,19) (LE: 3).

This paper also showed that Gleason 6-10 tumours carry a continuously increasing risk of ending the patient’s life for up to 15 years of follow-up after conservative management. The cancer-specific survival curves for this group of patients have been published in a recent discussion article on different methods of assessing outcome in treatment for localised PCa (18).

* The figures on the risk of cancer death differ for different age groups and represent the true risk in the studied population (taking actual competing mortality from other causes into consideration).
† The cancer-specific mortality compensates for differences in competing mortality and indicates the outcome if the patient actually lived for 15 years.

Three randomised clinical trials have reported long-term follow-up of patients randomised to WW or radical prostatectomy: the first was in the pre-PSA screening era (19); the second was at the beginning of PSA screening (20); and the third was a recent study, the results of which have been published in 2012 (21).

Between 1967 and 1975, the Veterans Administration Cooperative Urological Research Group randomised 142 patients affected by clinical localised PCa. The study was underpowered to detect treatment differences (22).

Between 1989 and 1999, the Scandinavian Prostate Cancer Group Study Number 4 (SPCG-4) randomised 695 patients with clinical stage T1-T2 to WW (n = 348) or radical prostatectomy (n = 347) (Table 11) (30). This study began after PSA screening was introduced into clinical practice, but only 5% of men were diagnosed by screening. After a median follow-up of 12.8 years, this study showed a significant decrease in cancer-specific mortality, overall mortality, metastatic risk progression and local progression in patients treated with radical prostatectomy versus WW (LE: 1b).

RP = radical prostatectomy; WW = watchful waiting.

Subgroup analysis showed that the overall difference was not modified by PSA level (below or above 10 ng/mL) or by the Gleason score (below 7 or above) at the time of diagnosis. However, age at that the time of randomisation had a profound impact, the benefit on overall survival and metastases free survival being only seen for those below 65 years of age.

The Prostate Cancer Intervention Versus Observation Trial: VA/NCI/AHRQ Cooperative Studies Program #407 (PIVOT) recruited 731 men with clinically organ confined prostate cancer to the arms of radical prostatectomy or WW (21). Inclusion criteria were clinically organ confined PCa (cT1-2cN0cM0) with a PSA < 50 ng/mL,
patient age < 75 years and a life expectancy > 10 years. It has to be considered that 50% of the men had a non-palpable PCa, which was only the case in 12% of the patients in the SPCG-4 trial (20). Both prostate biopsy and radical prostatectomy specimens were pathohistologically assessed by a reference pathologist.

After a mean follow-up of 10 years, no statistically significant between both treatment arms could be demonstrated with regard to overall mortality (47% versus 49.9%, p = 0.22) and PCa-specific survival (5.8% versus 8.4%, p = 0.09). There were also no statistically significant differences concerning overall survival between both treatment groups when considering patient age, Gleason Score, performance status, and Charlson comorbidity score. Only patients exhibiting a pre-treatment PSA serum concentration > 10 ng/ml or high risk PCa experienced a statistically significant benefit concerning overall survival with a relative risk reduction of mortality of 33% (p = 0.02) and 31% (p < 0.01), respectively. In the pooled analysis a relative risk reduction and an absolute risk reduction of 31% and 10.5%, respectively, was identified for patients with intermediate/high risk PCa (p < 0.01). Patients who underwent radical prostatectomy also experienced a statistically significant reduction concerning the development of bone metastases (4.7% versus 10.6%, p < 0.01).

No data are available comparing WW and radiotherapy. Some data are available for hormonal treatment. For patients who choose deferred treatment, there appears to be a modest risk of disease progression, although shorter cancer-specific survival times have been reported after deferred therapy compared with immediate hormone therapy, in presumed localised PCa (not using PSA for staging) after 15 years of follow-up (22). In contrast to Lundgren et al. (22), the report of the Casodex Early Prostate Cancer Trialists’ Group programme showed a higher mortality in a group of men with localised PCa treated with bicalutamide, 150 mg/day, than in those who received placebo (23).

Conclusions on deferred treatment

Clinical stage T1c currently represents 40-50% of new cases of PCa (24). The incidence of small, localised, well-differentiated PCa is increasing, mainly as a result of PSA screening and ‘multicore’ schemes of prostate biopsy.

The SPCG-4 study demonstrated significant advantages for RP over WW, but only 5% of those studied were PSA-screened patients.

During the past 20 years, there appears to have been a shift towards higher Gleason scoring levels (25), even in cases evaluating microscopic foci of PCa. Some tumours previously given a Gleason score of 6 (3 + 3) might be scored today as 7 (3 + 4) or higher.

The lead time in PSA screening is about 10 years (26,27). It is therefore possible that cancer-related mortality from untreated, non-screen-detected PCa in patients with contemporary Gleason scores of 6 might be as low as 10% at 20-year follow-up (28).

The comparison of immediate hormonal treatment to WW in localised PCa remain controversial and may be associated with an increased mortality with bicalutamide.

It appears that many small localised well-differentiated tumours will not progress, and radical therapy may lead to substantial overtreatment with resulting effects on the patients’ quality of life and treatments costs. This has been further confirmed by a recent analysis at 5 and 10 years of 19,639 patients > 65 years from the SEER database not given curative treatment. Based on comorbidities (Charlson score), most men with a Charlson score ≥ 2 died from competing causes at 10 years, whatever their initial age (below or above 65 years). However, men with no or just one comorbidity had a low risk of death at 10 years, especially for well or moderately differentiated lesions (29). In men with a Charlson score ≥ 2, tumour aggressiveness had little impact on overall survival, suggesting that perhaps these patients could have been spared the biopsies and diagnosis of cancer. This strengthens the major role of initial comorbidity evaluation, leading to an individual survival probability, before embarking an individual on any form of medical intervention such as biopsies or treatment (30).

8.2.2 Active surveillance

Active surveillance was conceived with the aim of reducing the ratio of overtreatment in patients with clinically confined very low-risk PCa, without giving up radical treatment, as happens with WW. Currently, the only data available is data from non-mature randomised clinical trials of active surveillance, with a follow-up of less than 10 years. Active surveillance can therefore only be proposed for highly selected low-risk patients, particularly as the data indicate there is a significant risk of tumour progression after conservative treatment for some patients with apparently localised PCa. This conclusion is also supported by other studies, which have shown that patients with a life expectancy > 10 years have a higher mortality rate from PCa in the absence of curative treatment. These studies include the Johansson series, which showed that there is a higher risk of dying from PCa in patients surviving more than 15 years with well- and moderately differentiated tumours at diagnosis.
In the light of these findings, it is essential that a more precise selection of candidates for active surveillance is carried out.

A multicentre clinical trial of active surveillance versus immediate treatment was opened in the USA in 2006. Its results are expected in 2025. Choo, Klotz and co-workers were the first to report on a prospective active surveillance protocol (32,33). The most advanced cohort to date was reported last year by Klotz (43). A total of 450 patients with clinical stage T1c or T2a, PSA \( \leq 10 \) ng/mL were enrolled with an overall Gleason score \( \leq 6 \) (PSA \( \leq 15 \)), with patients > 70 years having a Gleason score \( \leq 7 \) (3 + 4). Initially, six biopsies were performed, followed by the usual extended 12-core protocol during the study. At a median follow-up of 6.8 years, the 10-year overall survival was 68%. At 10 years, the disease-specific survival was 97.2%, with 62% of men still alive on active surveillance. Subsequently, 30% of patients underwent a radical treatment for the following reasons: 48% for a PSA doubling time < 3 years; 27% for Gleason score progression on repeat biopsies; and 10% because of patient preference.

A variety of additional studies on active surveillance in clinically organ confined disease (Tables 12 and 13) have now been published. All have confirmed that, in well-selected patients with very low-risk disease, there was a very low rate of progression and cancer-specific death, with only a few patients required delayed radical intervention. However, an extended follow-up is necessary to obtain definitive results. Thus, active surveillance might mean no treatment at all for patients older than 70 years, while in younger patients, it might mean a possible treatment delayed for years. The repeated biopsies that are part of active surveillance might then become important for their potential side effect on nerve preservation if surgery is subsequently considered.

Different series have identified several eligibility criteria for enrolment (41):

- clinically confined PCa (T1-T2);
- Gleason score < 7 for most studies;
- PSA < 10-15 ng/mL.

Limited tumour volume is defined by a low number of involved cores and a low tumour length on each involved core. The role of other tools, e.g. MRI, to better define acceptable lesions remains controversial, except
probably for anterior lesions (42). The PCA3 level may become a practical tool in the future (43).

Active surveillance is based on repeated DRE, PSA and most importantly repeated biopsies, usually every year. The place of early repeated biopsy has become an important part of the selection process, based on the risk of under-detection of grade 4 (35,40,44,45).

The criteria for active treatment are less well defined (5), but most groups have used:

- PSA doubling time with a cut-off value ranging between ≤ 2 and ≤ 4 years. This criterion is becoming questionable because of a weak link between PSA doubling time and grade progression on repeated biopsy (46).
- Gleason score progression to ≥ 7 during follow-up systematic biopsies, at intervals ranging from 1-4 years.
- Patient’s request mainly based on anxiety. This is a significant factor (36) and might affect up to 10% of treated patients. No data is available regarding active surveillance. However, data from the SPCG-4 trial has suggested that, based on self-administered questionnaires 87% of the included patients, the treatment group always reported inferior well-being, depression and psychological status, but this difference was never significant (47).

8.3 Deferred treatment for locally advanced PCa (stage T3-T4, Nx-N0, M0)

The literature reporting on deferred treatment for locally advanced PCa is sparse. There are no randomised studies that compare more aggressive treatments, such as radiotherapy or surgery, with or without hormones.

Most patients whose disease progresses after deferred treatment of locally advanced PCa will be candidates for hormone therapy. There are reports from non-randomised studies showing that hormone treatment may safely be delayed until metastatic progression occurs, as no survival advantage was noted between patients treated with immediate orchectomy compared with delayed treatment (48,49).

In a prospective randomised clinical phase III trial (EORTC 30981), 985 patients with T0-4 N0-2 M0 PCa were randomly assigned to immediate androgen-deprivation therapy (ADT) or received ADT only on symptomatic disease progression or occurrence of serious complications (50,51). After a median follow-up of 7.8 years, the overall survival hazard ratio was 1.25 (95% confidence interval [CI]: 1.05-1.48; non-inferiority p > 0.1) favouring immediate treatment, seemingly due to fewer deaths of non-prostatic cancer causes (p = 0.06). The time from randomisation to progression of hormone-refractory disease did not differ significantly nor did prostate cancer-specific survival. The median time to the start of deferred treatment after study entry was 7 years. In this group, 126 patients (25.6%) died without ever needing treatment (44% of deaths in this arm). The conclusion drawn from this study is that immediate ADT resulted in a modest but statistically significant increase in overall survival, but no significant difference in PCa mortality or symptom-free survival. This raises the question of the usefulness of such a small statistical benefit.

Furthermore, the authors identified significant risk factors associated with a significantly worse outcome: in both arms. Patients with a baseline PSA > 50 ng/mL were at a > 3.5-fold higher risk of dying of PCa than patients with a baseline PSA ≤ 8 ng/mL. If the baseline PSA was between 8 ng/mL and 50 ng/mL, the risk of PCa death was approximately 7.5-fold higher in patients with a PSA doubling time < 12 months than in patients with a PSA doubling time > 12 months. The time to PSA relapse following a response to immediate ADT correlated significantly with baseline PSA, suggesting that baseline PSA may also reflect disease aggressiveness.

However, when early and delayed treatments were compared in a large randomised trial carried out by the Medical Research Council (MRC), a survival benefit for immediate hormone therapy was demonstrated (62), comparable with the results of the Lundgren et al. study mentioned above (22) (LE: 1b). In addition, a comparison of bicalutamide, 150 mg/day, with placebo showed that progression-free survival (PFS) was better with early treatment in patients with locally advanced PCa (23) (LE: 1b).

Fifty selected asymptomatic patients (mean age 71 years) with highly or moderately differentiated stage T3 M0 PCa were followed up for 169 months (53). The 5- and 10-year cancer-specific survival rates were 90% and 74%, respectively, and the likelihood of being without treatment at 5 and 10 years was 40% and 30%, respectively. The authors concluded that WW might be a treatment option for selected patients with non-poorly differentiated T3 tumours and a life expectancy of less than 10 years (LE: 3).

8.4 Deferred treatment for metastatic PCa (stage M1)

There are only very sparse data on this subject. The only candidates for such treatment should be asymptomatic patients with a strong wish to avoid treatment-related side-effects (LE: 4). As the median survival time is about 2 years, the time without any treatment (before symptoms occur) is very short in most cases. The MRC trial highlighted the risk of developing symptoms (pathological fractures, spinal cord compression), and even death from PCa, without receiving the possible benefit from hormone treatment (52,54) (LE:1b). If a deferred treatment policy is chosen for a patient with advanced PCa, close follow-up must be possible.

9. TREATMENT: RADICAL PROSTATECTOMY

9.1 Introduction

The surgical treatment of prostate cancer (PCa) consists of radical prostatectomy (RP), which involves removal of the entire prostate gland between the urethra and bladder, and resection of both seminal vesicles, along with sufficient surrounding tissue to obtain a negative margin. Often, this procedure is accompanied by bilateral pelvic lymph node dissection. In men with localised PCa and a life expectancy ≥ 10 years, the goal of RP by any approach must be eradication of disease, while preserving continence and whenever possible potency (1). There is no age threshold for RP and a patient should not be denied this procedure on the grounds of age alone (2). Increasing comorbidity greatly increases the risk of dying from non-PCa-related causes (3). An estimation of life expectancy is paramount in counselling a patient about surgery (4).

Currently, RP is the only treatment for localised PCa to show a benefit for OS and cancer-specific survival (CSS), compared with conservative management, as shown in one prospective randomised trial (5). After a follow-up of 15 years, the SPCG-4 trial showed that RP was associated with a reduction of all-cause mortality: RR=0.75 (0.61 to 0.92). According to a post hoc statistical sub-group analysis, the number to treat (NNT) to avert one death was 15 overall and 7 for men younger than 65 years of age. Radical prostatectomy...
was also associated with a reduction in prostate cancer-specific mortality: RR=0.62 (0.44 to 0.87). This OS and CSS benefit could not be reproduced for the overall study population in another prospective randomised trial. After a median follow-up of 10 years, the PIVOT trial showed that RP did not significantly reduce all-cause mortality: HR=0.88 (0.71 to 1.08); p=0.22, nor did RP significantly reduce prostate cancer mortality: HR=0.63 (0.36 to 1.09); p=0.09. According to a preplanned sub-group analysis among men with low-risk tumours (n=296), RP non-significantly increased all-cause mortality: HR=1.15 (0.80 to 1.66). Among men with intermediate-risk tumours (n=249), RP significantly reduced all-cause mortality: HR=0.69 (0.49 to 0.98). Among men with high-risk tumours (n=157), RP non-significantly reduced all-cause mortality: HR=0.40 (0.16 to 1.00). Among men with PSA > 10, RP significantly reduced all cause mortality: HR=0.67 (0.48 to 0.94).

Surgical expertise has decreased the complication rates of RP and improved cancer cure (6-10). If performed by an experienced surgeon, the patient’s subsequent quality of life should be satisfactory. Lower rates of positive surgical margins for high-volume surgeons suggest that experience and careful attention to surgical details, adjusted for the characteristics of the cancer being treated, can decrease positive surgical margin rates and improve cancer control with RP (11,12).

Radical retropubic prostatectomy (RRP) and perineal prostatectomy are performed through open incisions, and more recently, minimally invasive laparoscopic radical prostatectomy (LRP) and robot-assisted laparoscopic prostatectomy (RALP) have been developed. RALP is displacing RRP as the gold standard surgical approach for clinically localised PCa in the United States and is also being increasingly used in Europe and other parts of the world. This trend has occurred despite the paucity of high-quality evidence to support its superiority over more-established treatment modalities. Recent in-depth systematic reviews of the literature have compared the results of RRP versus LRP/RALP.

Robot-assisted laparoscopic prostatectomy is associated with less blood loss and transfusion rates comparable to RRP, and there appear to be minimal differences between the two surgical approaches in terms of overall post-operative complications. Positive surgical margin rates are at least equivalent to RARP, but firm conclusions about biochemical recurrence and other oncologic end-points are difficult to draw due to the relatively short follow-up in the published literature and the fact that the overall experience with RARP in locally advanced PCa is still limited. RARP may offer advantages in postoperative recovery for urinary continence and erectile function, although most published studies addressing these outcomes suffer from methodological limitations. There is a need for well-controlled comparative outcomes studies of RP surgery following best practice guidelines.(13-17).

9.2  Low-risk, localised prostate cancer: cT1-T2a and Gleason score 2-6 and prostate-specific antigen < 10 ng/mL

Patients with low-risk, localised PCa should be informed about the results of two randomised trials comparing retropubic RP versus watchful waiting (WW) in localised PCa. In the SPCG-4 study, the survival benefit was similar before and after 9 years of follow-up and was also observed in men with low-risk PCa, and was confined to men < 65 years of age. In the PIVOT-trail, a preplanned sub-group analysis of men with low-risk tumours, showed that RP did not significantly reduce all-cause mortality.

9.2.1 Stage T1a-T1b prostate cancer

Stage T1a PCa is defined as an incidental histological finding of cancer in ≤ 5% of resected prostatic tissue [transurethral resection of the prostate (TURP) or open adenectomy]. Stage T1b PCa is defined as > 5% cancer. Published series have shown a pT0 stage in 4-21% and an organ-confined stage in 47-85% of patients at subsequent RP (18).

A Swedish register-based study of 23,288 men with incidental PCa detected at TURP or open adenoma enucleation, mostly the prostate-specific antigen (PSA) era, showed a 10-year PCa mortality of 26.6%. There were no details of the PSA level or Gleason score, nor the numbers of cases with cT1a or cT1b PCa (19). Other older studies have shown that, even though the risk of disease progression of untreated T1a PCa after 5 years is only 5%, these cancers can progress in about 50% of cases after 10-13 years (20). Thus, it was believed that, in younger patients with a life-expectancy of ≥ 15 years, the chance of disease progression was real. In contrast, most patients with T1b tumours were expected to show disease progression after 5 years, and aggressive treatment was often warranted (20). Patients with T1b lesions were offered RP when they had a life expectancy of ≥ 10 years.

Nevertheless, it remains unclear whether these findings would still be valid in the PSA era. In a recent analysis of T1a/b PCa:

- The only significant predictors of the presence of residual cancer at RRP were PSA measured before and after surgery for benign prostatic hyperplasia (BPH) and Gleason score at surgery for BPH.
- The only independent predictors of biochemical recurrence after RRP were PSA measured after
surgery for BPH and Gleason score at surgery for BPH.

• The stage (cT1a or cT1b) lost its significance in predicting the above-mentioned outcomes.

A predictive model has been proposed, which incorporates the PSA level before and after surgery and the Gleason score at surgery for BPH. The model has a predictive accuracy of 83.2% for estimating residual tumour and 87.5% for estimating biochemical progression, but needs external validation before it can be used in daily practice (18).

Systematic prostate biopsies of the remnant prostate may be useful in detecting residual cancer or concomitant peripheral zone cancer, or to ascertain a more correct tumour grade. Radical prostatectomy may be difficult after thorough TURP, when almost no residual prostate is left behind (21).

9.2.2 Stage T1c and T2a prostate cancer
Clinically unapparent tumour identified by needle biopsy because of an elevated PSA (cT1c) has become the most prevalent type of PCa. In an individual patient, it is difficult to differentiate between clinically insignificant and life-threatening PCa. Most reports, however, stress that cT1c tumours are mostly significant and should not be left untreated because up to 30% of cT1c tumours are locally advanced at final histopathological analysis (22). The proportion of insignificant tumours varies between 11% and 16% (23,24). Increasing the number of biopsies may carry the risk of detecting a higher number of insignificant cancers. However, a recent study has shown that increasing the number of biopsies to 12 did not increase the number of insignificant tumours (25). The major problem is how to recognise those tumours that do not need RP. The biopsy findings and the free PSA ratio are helpful in predicting insignificant disease (26). Partin tables may help better selection of patients who require surgical treatment, because of their ability to provide an estimation of the final pathological stage (27). Other authors have suggested the incorporation of biopsy information, such as the number of cores or the percentage of cores invaded (28). When only one or a few cores are invaded and the percentage of invasion in one core is limited, the chance of finding an insignificant PCa is more likely, certainly when the lesion is of low Gleason score (29). It might be reasonable to follow-up some patients whose tumours are most likely to be insignificant.

In general, however, RP should be advocated for patients with T1c tumours, bearing in mind that significant tumours will be found in most of these individuals. Stage T2a patients with a 10-year life expectancy should be offered RP because 35-55% of them will have disease progression after 5 years if not treated. If active monitoring is proposed for low-grade T2 cancer, it should be remembered that preoperative assessment of tumour grade by needle biopsy is often unreliable (30).

Extended pelvic lymph node dissection (eLND) is not necessary in low-risk, localised PCa, because the risk for positive lymph nodes does not exceed 5% (31).

9.3 Intermediate-risk, localised prostate cancer: cT2b-T2c or Gleason score = 7 or prostate-specific antigen 10-20 ng/mL
Patients with intermediate-risk, localised PCa should be informed about the results of two randomised trials comparing RRP vs. WW in localised PCa. In the SPCG-4 study, the survival benefit was similar before and after 9 years of follow-up and was confined to men < 65 years of age. The number needed to treat to avert one death was 15 overall and seven for men < 65 years of age. In the PIVOT-trial, a preplanned sub-group analysis of men with intermediate-risk tumours, RP did significantly reduce all-cause mortality. Radical prostatectomy is one of the recommended standard treatments for patients with intermediate-risk PCa and a life expectancy of > 10 years (32). The prognosis is excellent when the tumour is confined to the prostate, based on pathological examination (33,34). A policy of WW has been proposed for some patients with intermediate-risk localised tumours (35). However, when the tumour is palpable or visible on imaging and clinically confined to the prostate, disease progression can be expected in most long-term survivors. The median time to progression of untreated T2 disease has been reported as 6-10 years. Stage T2b cancer confined to the prostate, but involving more than half a lobe or both lobes, will progress in > 70% of patients within 5 years (36). These data have been confirmed by a large RCT which included mostly T2 PCa patients and compared RP and WW. The results showed a significant reduction in disease-specific mortality in favour of RP (5). Another large RCT corroborated these results (6).

An eLND should be performed in intermediate-risk, localised PCa if the estimated risk for positive lymph nodes exceeds 5% (31). In all other cases, eLND can be omitted, which means accepting a low risk of missing positive nodes. Limited LND should no longer be performed, because this misses at least half of the nodes involved.
9.3.1 **Oncological results of radical prostatectomy in low- and intermediate-risk prostate cancer**

The results achieved in a number of studies involving RP are shown in Table 14.

**Table 14: Oncological results of RP in organ-confined disease**

The first externally validated nomogram predicting PCa-specific mortality after RP for patients treated in the PSA era was published in 2009. The nomogram predicts that few patients die from PCa within 15 years of RP, despite the presence of adverse clinical features. This nomogram can be used in patient counselling and clinical trial design (42).

9.4 **High-risk localised and locally advanced prostate cancer: cT3a or Gleason score 8-10 or prostate-specificantigen > 20 ng/mL**

The widespread use of PSA testing has led to a significant migration in stage and grade of PCa, with > 90% of men in the current era diagnosed with clinically localised disease (27). Despite the trends towards lower-risk PCa, 20-35% of patients with newly diagnosed PCa are still classified as high risk, based on either PSA > 20 ng/mL, Gleason score > 8, or an advanced clinical stage (43). Patients classified with high-risk PCa are at an increased risk of PSA failure, the need for secondary therapy, metastatic progression and death from PCa. Nevertheless, not all high-risk PCa patients have a uniformly poor prognosis after RP (44).

There is no consensus regarding the optimal treatment of men with high-risk PCa. Decisions on whether to elect surgery as local therapy should be based on the best available clinical evidence. Provided that the tumour is not fixed to the pelvic wall, or that there is no invasion of the urethral sphincter, RP is a reasonable first step in selected patients with a low tumour volume. Management decisions should be made after all treatments have been discussed by a multidisciplinary team (including urologists, radiation oncologists, medical oncologists and radiologists), and after the balance of benefits and side effects of each therapy modality has been considered by the patients with regard to their own individual circumstances.

9.4.1 **Locally advanced prostate cancer: cT3a**

Stage T3a cancer is defined as cancer that has perforated the prostate capsule. In the past, locally advanced PCa was seen in about 40% of all clinically diagnosed tumours. This figure is lower today, although its management remains controversial. Surgical treatment of clinical stage T3 PCa has traditionally been discouraged (45), mainly because patients have an increased risk of positive surgical margins and lymph node metastases and/or distant relapse (46,47). Several randomised studies of radiotherapy combined with ADT versus radiotherapy alone have shown a clear advantage for combination treatment, but no trial has ever proven combined treatment to be superior to RP (48). Another problem is “contamination” by the additional use of either adjuvant radiotherapy or immediate or delayed hormonal therapy (HT) in most series reporting the treatment of clinical T3 PCa. In recent years, there has been renewed interest in surgery for locally advanced PCa, and several retrospective case series have been published. Although still controversial, it is increasingly evident that surgery has a place in treating locally advanced disease (49-51).
Over-staging of cT3 PCa is relatively frequent and occurs in 13-27% of cases. Patients with pT2 disease and those with specimen-confined pT3 disease have similarly good biochemical and clinical PFS (50,51). In 33.5-66% of patients, positive section margins are present, and 7.9-49% have positive lymph nodes (52). Thus, 56-78% of patients primarily treated by surgery eventually require adjuvant or salvage radiotherapy or HT (50,51). Nevertheless, excellent 5-, 10- and 15-year OS and CSS rates have been published (Table 15). These rates surpass radiotherapy-alone and are no different from radiotherapy combined with adjuvant HT (48).

The problem remains the selection of patients before surgery. Nomograms, including PSA level, stage and Gleason score, can be useful in predicting the pathological stage of disease (27,52). In addition, nodal imaging with CT, and seminal vesicle imaging with MRI, or directed specific puncture biopsies of the nodes or seminal vesicles can help to identify those patients unlikely to benefit from a surgical approach (53). Radical prostatectomy for clinical T3 cancer requires sufficient surgical expertise to keep the level of morbidity acceptable. Increased overall surgical experience must contribute to decreased operative morbidity and to better functional results after RP for clinical T3 cancer (50,54). It has been shown that continence can be preserved in most cases, and in selected cases, potency can also be preserved (55).

BPFS = biochemical progression-free survival

**9.4.2 High-grade prostate cancer: Gleason score 8-10**

Although most poorly differentiated tumours extend outside the prostate, the incidence of organ-confined disease is 26-31%. Patients with high-grade tumours confined to the prostate at histopathological examination still have a good prognosis after RP. Furthermore, one-third of patients with a biopsy Gleason score ≥ 8 may in fact have a specimen Gleason score ≤ 7 with better prognostic characteristics. The PSA value and percentage of positive prostate biopsies may help to select men with high-grade PCa who are most likely to benefit from RP (56).

**9.4.3 Prostate cancer with prostate-specific antigen > 20 ng/mL**

Yossepowitch et al. have reported the results of RP as monotherapy in men with PSA > 20 ng/mL, in a cohort with mostly clinically organ-confined tumours, and found a PSA failure rate of 44% and 53% at 5 and 10 years, respectively (44). D’Amico et al. found that men with PSA levels > 20 ng/mL had a 50% risk of PSA failure at 5 years after RP (57). Spahn et al. published the largest multicentre surgical series to date, including 712 patients with PSA > 20 ng/mL, and reported a CSS of 90% and 85% at 10 and 15 years follow-up, respectively (58). In the same analysis, they demonstrated that the combination of PSA > 20 ng/mL with cT3 stage and/or biopsy Gleason score 8-10 significantly lowered CSS. More recently, Gontero and co-workers described a subanalysis of the same patient cohort. Ten-year CSS was 80%, 85% and 91% in patients with PSA > 100 ng/mL, 50.1-100 ng/mL and 20.1-50 ng/mL, respectively. These results argue for aggressive management with RP as the initial step (59).

Extended LND should be performed in all high-risk cases, because the estimated risk for positive lymph nodes is 15-40% (31). Limited LND should no longer be performed, because it misses at least half the nodes involved.

**9.5 Very-high-risk, localised prostate cancer: cT3b-T4 N0 or any T, N1**

**9.5.1 cT3b-T4 N0**

Men with very-high-risk PCa generally have a significant risk of disease progression and cancer-related death
if left untreated. Very-high-risk PCa presents two specific challenges. There is a need for local control as well as treatment of any microscopic metastases that are likely to be present but undetectable until disease progression.

The optimal treatment approach therefore often necessitates multiple modalities. The exact combinations, timing and intensity of treatment continue to be strongly debated. A recent US study has shown that 72 patients who underwent RP for cT4 disease had better survival than those who received HT or radiotherapy alone, and comparable survival to men who received radiotherapy plus HT (60). Another study has compared the outcomes of RP in very-high-risk PCa (T3-T4 N0-N1, N1, M1a) with those in localised PCa. The two groups did not differ significantly in surgical morbidity except for blood transfusion, operative time, and lymphoceles, which showed a higher rate in patients with advanced disease. Overall survival and CSS at 7 years were 76.69% and 90.2% in the advanced disease group and 88.4% and 99.3% in the organ-confined disease group, respectively (61).

Provided that the tumour is not fixed to the pelvic wall, or there is no invasion of the urethral sphincter, RP is a reasonable first step in selected patients with very-high-risk PCa and low tumour volume. Management decisions should be made after all treatments have been discussed by a multidisciplinary team (including urologists, radiation oncologists, medical oncologists and radiologists), and after the balance of benefits and side effects of each therapy modality has been considered by the patients with regard to their own individual circumstances.

9.5.2 Any T, N1

The indication for RP in all previously described stages assumes the absence of clinically detectable nodal involvement. Clinical lymph node-positive (N+) disease will mostly be followed by systemic disease progression, and all patients with significant N+ disease ultimately fail treatment.

Nevertheless, the combination of RP and early adjuvant HT in pN+ PCa has been shown to achieve a 10-year CSS rate of 80% (62,63). Most urologists are reluctant to perform RP for clinical N+ disease, or cancel surgery if a frozen section shows lymph node invasion. However, a retrospective observational study has shown a dramatic improvement in CSS and OS in favour of completed RP vs. abandoned RP in patients who were found to be N+ at the time of surgery. These results suggest that RP may have a survival benefit and the abandonment of RP in N+ cases may not be justified (64). These findings have been corroborated in a contemporary retrospective analysis (65). Radical prostatectomy resulted in superior survival of patients with N+ PCa after controlling for lymph node tumour burden. The findings from these studies support the role of RP as an important component of multimodal strategies of N+ PCa.

The incidence of tumour progression is lower in patients with fewer positive lymph nodes and in those with microscopic invasion only (66,67). In patients who prove to be pN+ after RP, early adjuvant HT has been shown to improve CSS and OS significantly in a prospective randomised trial. However, this trial included mostly patients with high-volume nodal disease and multiple adverse tumour characteristics. It is unclear whether early adjuvant HT should still be used in the present era of increased detection of microscopic involvement as a result of more eLND. The benefits should be judged against the side effects of long-term HT. Follow-up of PSA and delayed start of HT in patients with rising PSA level is therefore an acceptable option in selected cases. Interestingly, maximal local control with radiotherapy of the prostatic fossa appears to be beneficial in PCa patients with pN+ after RP, treated adjuvantly with continuous ADT (68).

9.6 Indication and extent of extended pelvic lymph node dissection

Although it is generally accepted that eLND provides important information for prognosis (number of nodes involved, tumour volume within the lymph node, and capsular perforation of the node) that cannot be matched by any other current procedure, consensus has not been reached about when eLND is indicated and to what extent it should be performed. When making such decisions, many physicians rely on nomograms based on preoperative biochemical markers and biopsies (27).

According to these nomograms, patients with PSA < 10 ng/mL and biopsy Gleason score < 7 have a low risk of lymph node metastasis, and therefore, eLND might not be beneficial. However, the fact that most nomograms are based on a limited eLND (obturator fossa and external iliac vein) probably results in underestimation of the incidence of patients with positive nodes (31). Lymphography studies have shown that the prostate drains not only to the obturator and external iliac lymph nodes but also to the internal iliac and presacral nodes. Performing eLND results in removal of all lymph nodes in these particular anatomical regions, producing a higher yield of excised lymph nodes (mean: 20 nodes) compared with limited LND (mean: 8-10 nodes).

In patients with PSA < 10 ng/mL and Gleason score ≥ 7, the incidence of nodal involvement has been reported as 25% (69). Different reports mention that 19-35% of positive lymph nodes are found exclusively outside the area of the traditionally limited LND (70,71). Clearly, the removal of a greater number of nodes results in improved staging. In the largest study of its kind, a cut-off ≤ 2 vs. > 2 affected nodes was shown to
be an independent predictor of CSS (66).

9.6.1 **Extent of extended lymph node dissection**

Extended LND includes removal of the nodes overlaying the external iliac artery and vein, the nodes within the obturator fossa located cranially and caudally to the obturator nerve, and the nodes medial and lateral to the internal iliac artery. Some lymph node mapping studies have advocated extending the template to include the common iliac lymph nodes up to the ureteric crossing. With this template, 75% of all anatomical landing sites are cleared (72). For eLND to be representative, a mean of 20 lymph nodes should be removed (73). It is recommended that the nodes should be sent in separate containers for each region for histopathological analysis, because this will usually be associated with a higher diagnostic gain by the uropathologist.

9.6.2 **Therapeutic role of extended lymph node dissection**

Besides being a staging procedure, pelvic LND/eLND can be curative, or at least beneficial, in a subset of patients with limited lymph node metastases (74-76). In some series, the number of nodes removed during lymphadenectomy has correlated significantly with time to progression (77). In one population-based study with a 10-year follow-up, patients undergoing excision of at least four lymph nodes (node-positive and node-negative patients) or > 10 nodes (only node-negative patients) had a lower risk of PCa-specific death at 10 years than those who did not undergo lymphadenectomy (78). Further studies should confirm these results.

9.6.3 **Morbidity**

Pelvic eLND remains a surgical procedure that increases morbidity in the treatment of PCa. When comparing extended vs. limited LND, threefold higher complication rates have been reported by some authors (79). Complications consist of lymphocoeles, lymphoedema, deep venous thrombosis, and pulmonary embolism. Other authors, however, have reported more acceptable complication rates (80,81).

9.6.4 **Conclusions extended lymph node dissection**

| Extended LND may play a role in the treatment of a subset of intermediate-risk cases with > 5% nomogram predicted risk of positive lymph nodes, and in all high-risk cases. |
| Extended LND may increase staging accuracy and influence decision making with respect to adjuvant therapy. The number of lymph nodes removed correlates with time to progression. |
| Surgical morbidity must be balanced against the therapeutic effects, and decisions need to be made based on an individual cases. |

9.7 **Summary of radical prostatectomy and eLND in high-risk localised disease**

| RP is a reasonable treatment option in selected patients with cT3a PCa, Gleason score 8-10 or PSA > 20. Furthermore, RP is optional in highly selected patients with cT3b-4 N0 or any cT N1 PCa in the context of a multimodality approach. |
| Management decisions should be made after all treatments have been discussed by a multidisciplinary team (including urologists, radiation oncologists, medical oncologists and radiologists), and after the balance of benefits and side effects of each therapy modality has been considered by the patients with regard to their own individual circumstances. |
| If RP is performed, pelvic eLND must be performed, because lymph node involvement is common. |
| The patient must be informed about the likelihood of a multimodal approach. In case of adverse tumour characteristics (positive section margin, extraprostatic extension, or seminal vesicle invasion), adjuvant radiotherapy may reasonably be used after recuperation from surgery. |
| When nodal involvement is detected after surgery, adjuvant ADT may be selected. |
| Extended LND is not necessary in low-risk, localised PCa, because the risk for positive lymph nodes does not exceed 5%. |
| Extended LND should be performed in intermediate-risk, localised PCa if the estimated risk for positive lymph nodes exceeds 5%, as well as in high-risk cases. In these circumstances, the estimated risk for positive lymph nodes is 15-40%. |
| Limited LND should no longer be performed, because it misses at least half the nodes involved. |

RP = radical prostatectomy; PCa = prostate cancer; eLND = extended lymph node dissection; ADT = androgen-deprivation therapy.
9.8 Neoadjuvant hormonal therapy and radical prostatectomy

Neoadjuvant or up-front HT is defined as therapy given before definitive local curative treatment (e.g., surgery or radiotherapy). PCa is an androgen-dependent tumour, therefore, neoadjuvant hormonal therapy (NHT) is an appealing concept. Attempts to decrease the size of the prostate before RP were first reported by Vallett as early as 1944 (82). In a recent review and meta-analysis, the role of NHT and prostatectomy has been studied (83). NHT before prostatectomy did not improve OS or disease-free survival (DFS), but did significantly reduce positive margin rates [relative risk (RR): 0.49; 95% confidence interval (CI): 0.42-0.56, P < 0.00001], organ confinement (RR: 1.63; 95% CI: 1.37-1.95, P < 0.0001) and lymph node invasion (RR: 0.49; 95% CI: 0.42-0.56, P < 0.02). Thus, the absence of improvement in clinically important outcomes (OS, disease-specific survival or biochemical DFS) was demonstrated despite improvements in putative pathological surrogate outcomes, such as margin-free positive status. This calls into question the use of these pathological markers of treatment outcomes as valid surrogates for clinically relevant outcomes.

Further studies are needed to investigate the application of HT as both neoadjuvant treatment and with chemotherapy in early disease. More information is also needed to evaluate these agents in terms of side effects and quality of life, which was lacking in most studies presented in this review.

Further cost analyses should be undertaken to update the data. A recent Cochrane review and meta-analysis have studied the role of adjuvant HT following RP: the pooled data for 5-year OS showed an odds ratio (OR) of 1.50 and 95% CI: 0.79-2.84. This finding was not statistically significant, although there was a trend favouring adjuvant HT. Similarly, there was no survival advantage at 10 years. The pooled data for DFS gave an overall OR of 3.73 and 95% CI: 2.3-6.03. The overall effect estimate was highly significant (P < 0.00001) in favour of the HT arm.

It is noteworthy that the Early Prostate Cancer Trialists’ Group (EPC) trial was not included in the Cochrane review. The third update from this large randomised trial of bicalutamide, 150 mg once daily, in addition to standard care in localised and locally advanced, non-metastatic PCa was published in November 2005 (84). Median follow-up was 7.2 years. There was a significant improvement in objective PFS in the RP group. This improvement was only significant in the locally advanced disease group [hazard ratio (HR): 0.75; 95% CI: 0.61-0.91]. There was no significant improvement in OS in the RP-treated groups (localised and locally advanced disease). In the WW group, there was an OS trend in favour of WW alone in the localised disease group (HR: 1.16; 95% CI: 0.99-1.37).

9.8.1 Summary of neoadjuvant and adjuvant hormonal treatment and radical prostatectomy

| NHT before RP does not provide a significant OS advantage over prostatectomy alone. |
| NHT before RP does not provide a significant advantage in DFS over prostatectomy alone. |
| NHT before RP does substantially improve local pathological variables such as organ-confined rates, pathological down-staging, positive surgical margins, and rate of lymph node involvement. |
| Adjuvant HT following RP shows no survival advantage at 10 years. |
| Adjuvant HT following RP: the overall effect estimate for DFS is highly significantly (P < 0.00001) in favour of the HT arm. |

9.9 Complications and functional outcome

The postoperative complications of RP are listed in Table 16. The mortality rate is 0-1.5% (81); urinary fistulae are seen in 1.2-4% of patients (85); and urinary incontinence persists after 1 year in 7.7% (86). In men undergoing prostatectomy, the rates of postoperative and late urinary complications are significantly reduced if the procedure is performed in a high-volume hospital and by a surgeon who performs a large number of such procedures (87-89).

Erectile dysfunction used to occur in nearly all patients, but this can be avoided by using nerve-sparing techniques in early-stage disease (90). Patients who benefit from nerve-sparing RP may have a higher chance of local disease recurrence and should therefore be selected carefully.

*Clinical criteria used by different authors when NOT to perform a nerve-sparing RP

Nerve-sparing RP can be performed safely in most men undergoing RP (96,97). In the past decade, a dramatic shift towards lower-stage tumours has become evident. More importantly, men are younger at the time of diagnosis and more interested in preserving sexual function. Nevertheless, clear contraindications are patients in whom there is a high risk of extracapsular disease, such as any cT3 PCa, cT2c, any Gleason score > 7 on biopsy, or more than one biopsy > 6 at the ipsilateral side. Partin tables help to guide decision making (27).

If any doubt remains regarding residual tumour, the surgeon should remove the neurovascular bundle (NVB). Alternatively, the use of intraoperative frozen-section analysis can help guide these decisions. This is especially helpful in patients with a lesion palpable close to the capsule during nerve-sparing RP. A wedge of the prostate can then be resected and inked differently. In case carcinoma is adherent to the capsule on frozen section analysis, the NVB is resected; otherwise, the NVB remains in situ. In patients with intraoperatively detected tumour lesions during nerve-sparing, planned RP, frozen-section analysis objectively supports the decision of secondary NVB resection, as well as preservation (98).

The patient must be informed before surgery about the risks of nerve-sparing surgery, the potency rates achieved, and the possibility that, to ensure adequate cancer control, the nerves may be sacrificed despite any preoperative optimism favouring the potential for their salvage.
The early administration of intracavernous injection therapy could improve the definitive potency rates (99,100). Finally, the early use of phosphodiesterase-5 inhibitors in penile rehabilitation remains controversial. A placebo-controlled prospective study has shown no benefit from daily early administration of vardenafil vs. on-demand vardenafil in the postoperative period (101), whereas another placebo-controlled prospective study has shown that sildenafil has a significant impact on return of normal spontaneous erections (102).

10. TREATMENT: DEFINITIVE RADIOTHERAPY

10.1 Introduction

There have been no randomised studies comparing RP with either external-beam radiotherapy (EBRT) or brachytherapy for localised PCa. The National Institutes of Health (NIH) consensus statement in 1988 (1) stated that external irradiation offers the same long-term survival results as surgery; moreover, EBRT provides a quality of life (QoL) at least as good as that following surgery (2). A more recent systematic review has provided a more sophisticated overview of outcomes from reports that meet the criteria for stratifying patients by risk group, standard outcome measures, numbers of patients, and minimum median follow-up period (3). Radiotherapy continues to be an important and valid alternative to surgery as the sole form of curative therapy.

Intensity-modulated radiotherapy (IMRT), with or without image-guided radiotherapy (IGRT), is the gold standard for external-beam radiotherapy, and all centres that are unable to offer this should have a plan to introduce it as a routine method for the definitive treatment of prostate cancer.

In addition to external irradiation, transperineal low-dose or high-dose rate brachytherapy are widely used. In localised and locally advanced PCa, several randomised phase III trials conducted by the Radiation Therapy Oncology Group (RTOG) and European Organization for Research and Treatment of Cancer (EORTC) have established the indications for the combination of external irradiation and ADT.

Whatever the technique used, the choice of treatment - after the appropriate assessment of the extent of the tumour - must be based on a multidisciplinary approach and should take the following into account:

- 2009 TNM classification.
- Gleason score, defined using an adequate number of core biopsies (at least 12).
- Baseline prostate-specific antigen (PSA).
- Age of the patient.
- Patient's comorbidity, life expectancy, and QoL.
- International Prostate Symptom Score (IPSS) and uroflowmetry recordings.
- National Comprehensive Cancer Network (NCCN) and/or D'Amico prognostic factor classification (4).

Additional information on the various aspects of radiotherapy in the treatment of PCa is available in an extensive published overview (5).

10.2 Technical aspects: three-dimensional conformal radiotherapy (3D-CRT) and intensity-modulated external-beam radiotherapy (IMRT)

Anatomic data acquired by scanning the patient in a treatment position are transferred to the three-dimensional treatment planning system, which visualises the clinical target volume and then adds a surrounding safety margin. Real-time verification of the irradiation field by means of portal imaging allows comparison of the treated and simulated fields, and correction of deviations where displacement is more than 5 mm. Three-dimensional CRT improves local control through dose escalation, without significantly increasing the risk of morbidity.

It is possible to use IMRT with linear accelerators equipped with the latest multileaf collimators and specific software. At the time of irradiation, a multileaf collimator automatically - and in the case of IMRT continuously - adapts to the contours of the target volume seen by each beam; this allows for a more complex distribution of the dose to be delivered within the treatment field and provides concave isodose curves, which are particularly useful as a means of sparing the rectum. To date, no randomised trials have been published.
comparing dose escalation using IMRT and 3D-CRT.

With dose escalation using IMRT, organ movement becomes a critical issue, in terms of both tumour control and treatment toxicity. Evolving techniques will therefore combine IMRT with some form of IGRT, in which organ movement can be visualised and corrected for in real time, although the optimum means of achieving this is still unclear (6).

Another evolving technique for the delivery of IMRT is tomotherapy, which uses a linear accelerator mounted on a ring gantry that rotates as the patient is delivered through the centre of the ring, analogous to spiral CT scanning. Preliminary data suggest that this technique is feasible in PCa treatment (7).

Whatever the techniques and their degree of sophistication, quality assurance plays a major role in the management of radiotherapy, requiring the involvement of physicians, physicists, dosimetrists, radiographers, radiologists, and computer scientists.

10.3 Radiotherapy for localised prostate cancer

10.3.1 Dose escalation

Before the advent of 3D-CRT, radiotherapy doses to the prostate were usually in the order of 64 Gy in 2-Gy fractions, or equivalent. With 3D-CRT, and more recently IMRT, dose escalation beyond this limit has been possible. Several randomised studies have shown that dose escalation (range 76-80 Gy) has a significant impact on the 5-year survival without biochemical relapse (8-14). These trials have generally included patients from several risk groups, and the use of neoadjuvant/adjuvant hormone therapy (see below) has varied.

To date, no trials have yet shown that dose escalation results in an OS benefit, but the trials have shown a remarkable consistency in that they have all reported improvements in freedom from biochemical progression in patients treated with dose-escalated radiotherapy:

- The M.D. Anderson study compared 78 Gy with 70 Gy conventional radiotherapy. It included 305 stage T1-3 patients with a pre-treatment PSA level of more than 10 ng/mL, with a median follow-up period of 9 years. At 10 years after treatment, 16% of the high-risk patients treated with 70 Gy had died of disease, in comparison with 4% of patients treated with 78 Gy (P = 0.05), a percentage similar to that for patients with higher PSA values, 15% vs. 2% (P = 0.03) (8).

- The PROG 95-09 study evaluated 393 T1b-T2b patients, 75% of whom had a Gleason score ≤ 6 and a PSA level < 15 ng/mL. The patients were randomly assigned to receive an initial boost to the prostate alone, using conformal protons, of either 19.8 Gy or 28.8 Gy, and then 50.4 Gy to a larger volume. With a median follow-up period of 8.9 years, there was a significant difference in the 10-year American Society for Radiation Oncology (ASTRO) biochemical failure rate, at 32.4% for conventional-dose treatment (70.2 Gy) and 16.7% for high-dose treatment (79.2 Gy) (P < 0.0001). The difference persisted when only low-risk patients (58% of the total) were examined: 28.2% for conventional and 7.1% for high-dose treatment (P < 0.0001) (9).

- The MRC RT01 study, comparing a dose of 64 Gy with 74 Gy, both with neoadjuvant hormonal therapy, in 843 men with T1b-T3b disease, showed an 11% difference in the 5-year biochemical disease-free survival (BDFS) in favour of dose-escalated radiotherapy (P = 0.0007) (15).

- The Dutch randomised phase III trial comparing 68 Gy with 78 Gy showed a significant increase in the 5-year rate of freedom from clinical or biochemical failure in patients treated with a higher dose of radiotherapy (P = 0.02) (11).

- The phase III trial of the French Federation of Cancer Centres compared 70 Gy with 80 Gy in men with localised prostate cancer, in 306 patients with a pelvic lymph node involvement risk of < 10% (Partin) or pN0, with no hormonal therapy allowed before, during, or after radiotherapy. With a median follow-up period of 61 months, better 5-year biological outcomes were seen in favor of dose-escalated radiotherapy (P = 0.036) (12).

In everyday practice, a minimum dose of ≥ 74 Gy is recommended for EBRT + hormone therapy (expert opinion). Currently, it is not possible to make different recommendations by risk group, as there is evidence from these randomised trials for an impact of dose-escalation in low-risk, medium-risk, and high-risk patients, although probably of different magnitudes (10).

10.3.2 Neoadjuvant or adjuvant hormone therapy plus radiotherapy

Several randomised trials have shown clearly that in at least some patients with nonmetastatic prostate cancer, radiotherapy alone is inferior to the combination of radiotherapy plus ADT:

- EORTC study 22863 recruited 415 patients diagnosed with T1-2 grade 3 World Health Organization (WHO) or T3-4 N0 M0 and any histological grade, and compared radiotherapy plus adjuvant ADT with radiotherapy alone. Androgen deprivation treatment was allowed in cases of relapse. A total of 82% of patients were diagnosed as T3, 10% as T4, and 89% as N0. Hormonal treatment consisted of oral cyproterone acetate (CPA) 50 mg three times daily for 1 month, beginning 1 week before the start of radiotherapy, and goserelin acetate (Zoladex), 3.6 mg subcutaneously every 4 weeks for 3
years, starting on the first day of radiotherapy. The pelvic target volume received was 50 Gy, and the prostatic target volume was 20 Gy. With a median follow-up period of 66 months, the combination therapy compared with radiotherapy alone yielded significantly better survival (78% vs. 62%; P = 0.001) (16). At a median follow-up of 9.1 years, the 10-year OS remained significantly higher at 58.1% versus 39.8% (P < 0.0001), as did the clinical PFS at 47.7% vs. 22.7% (P < 0.0001). The 10-year cumulative incidences of PCa mortality were 11.1% vs. 31% (P < 0.0001), and the 10-year cumulative incidences of cardiovascular mortality were 11.1% vs. 8.2% (P = 0.75) (17).

- **RTOG study 8531** recruited 977 patients diagnosed with T3-4 N0-1 M0, or pT3, after RP. Androgen deprivation therapy was begun in the last week of irradiation and continued up to relapse (Group I) or was started at recurrence (Group II). A total of 15% of patients in Group I and 29% in Group II had undergone RP, and 14% of patients in Group I and 26% in Group II were pN1. Goserelin acetate, 3.6 mg subcutaneously, was administered every 4 weeks. The pelvis was irradiated with 45 Gy, while the prostatic target received 20-25 Gy. Patients diagnosed with stage pT3 received 60-65 Gy. With a median follow-up time of 7.6 years for all patients, the 10-year OS was significantly greater for the adjuvant arm, at 49% vs. 39% (P = 0.002) (18).

- **RTOG study 86-10** included 471 patients with bulky (5 x 5 cm) tumours T2-4 N0-X M0. Androgen deprivation therapy was administered at 2 months before irradiation and during irradiation, or in the case of relapse in the control arm. Thirty-two percent of the patients were diagnosed as having T2, 70% as having T3-4, and 91% with N0. The hormone treatment consisted of oral flutamide (Eulexin), 250 mg three times daily, and goserelin acetate (Zoladex), 3.6 mg every 4 weeks by subcutaneous injection. The pelvic target volume received 45 Gy and the prostatic target volume received 20-25 Gy. The 10-year OS estimates were 43% for ADT plus irradiation vs. 34% for hormonal treatment, although the difference was not significant (P = 0.12). There was a significant improvement in the 10-year disease-specific mortality (23% vs. 36%; P = 0.01), disease-free survival (11% vs. 3%; P < 0.0001) and in the biochemical failure rate (65% vs. 80%; P < 0.0001), with the addition of ADT having no statistical impact on the risk of fatal cardiac events (19).

- **A phase III randomised trial** including 206 patients with a PSA level of at least 10 ng/mL (maximum 40 ng/mL), a Gleason score of at least 7 (range 7-10), or radiographic evidence of extra-prostatic disease, compared 3D-CRT alone or in combination with 6 months of ADT. After a median follow-up period of 7.6 years, intermediate-risk or high-risk patients without moderate or severe comorbidity who had been randomly assigned to receive 3D-CRT + ADT showed a 13% improvement in the OS rate (P < 0.001) (20).

- **The RTOG 94-08 trial**, including 1979 patients with T1b-T2b and PSA < 20 ng/mL, showed that adding a complete androgen blockade for 2 months before and 2 months during conventional lower-dose radiotherapy (66 Gy) significantly improved the 10-year OS rate (62% vs. 57%; P = 0.03) (13). These trials included patients with a wide range of clinical risk factors, most of whom were thought to be at high risk of disease progression, usually by virtue of their clinical stage, but in some instances because of their PSA level or Gleason grade. The most powerful conclusion from these studies comes from the EORTC 22863 study, which is the basis for the combination of radiotherapy and ADT in patients with locally advanced (T3-T4) nonmetastatic prostate cancer. Whether these results should be applied to patients with all stages of prostate cancer is unclear.

- **EORTC trial 22991**, comparing 3D-CRT with or without IMRT with a choice of three levels of dosage (70 Gy, 74 Gy, or 78 Gy), with or without 6 months of neoadjuvant and concomitant hormonal therapy, was closed in April 2008 after recruiting 800 patients; the results are awaited.

10.3.2.1 Duration of adjuvant or neoadjuvant ADT in combination with radiotherapy.

Several phase III trials have attempted to define the optimum timing and/or duration of ADT in combination with radiotherapy.

- **The EORTC-22961 randomised phase III trial**, comparing 36 months of hormonal treatment plus radiotherapy with 6 months of hormonal treatment plus radiotherapy in 970 patients, showed that increased hormonal treatment improved OS in patients with high-risk PCa after 5 years (14). The 5-year overall mortality rates for short-term and long-term suppression were 19.0% and 15.2%, respectively; the observed hazard ratio was 1.42 (upper 95.71% confidence limit, 1.79; P = 0.65 for non-inferiority).

- **The Trans-Tasman Oncology Group (TROG) randomised trial** compared no neoadjuvant ADT with 3 months or 6 months of neoadjuvant ADT with goserelin and flutamide starting 2 months before radiotherapy, or 6 months of ADT with the same regimen starting 5 months before RT, in 818 men with T2b-T4 N0 M0 prostate cancer. While 3 months of ADT improved the biochemical PFS in comparison with radiotherapy alone, 6 months additionally improved the prostate cancer-specific survival and OS (21).
• The RTOG 94-13 randomised trial used a 2 × 2 design comparing whole-pelvic with prostate-only radiotherapy (see below) and neoadjuvant with adjuvant ADT in 1323 patients with stages T1c-T4 N0 M0 prostate cancer, and found no differences in the PFS. The report does, however, describe interactions between the timing of ADT and the radiotherapy volume, in subgroup analyses (22).

• The RTOG 92-02 study compared 4 months of neoadjuvant ADT (2 months before and during radiotherapy) with the same plus an additional 24 months of adjuvant ADT in 1554 men with T2c-T4 prostate cancer and reported improvements in local progression, disease-free survival, biochemical survival, and metastasis-free survival in patients treated with additional adjuvant ADT. However, an OS benefit was restricted to men with a Gleason score of 8-10 in the subgroup analysis (23).

10.3.2.2 Combined dose-escalated RT and ADT
Zelefsky et al. (24) reported a retrospective analysis of 2251 patients with T1-3 N0-X M0 PCa consisting of 571 low-risk patients (22.4%), 1074 intermediate-risk patients (42.1%), and 906 high-risk patients (35.5%), according to the National Comprehensive Cancer Network classification. Three-dimensional conformal radiotherapy or IMRT were administered to the prostate and seminal vesicles only. The prostate dose ranged from 64.8 to 86.4 Gy; doses beyond 81 Gy were delivered during the last 10 years using image-guided IMRT. Androgen deprivation therapy by complete androgen blockade with a luteinising hormone-releasing hormone (LHRH) agonist plus oral antiandrogen was administered, at the discretion of the treating physician, to 1249 patients (49%), including 623 high-risk patients (69%), 456 intermediate-risk patients (42%), and 170 low-risk (30%) patients. The duration of ADT was 3 months for low-risk patients and 6 months for intermediate-risk and high-risk patients, starting at 3 months before radiotherapy and continued during radiotherapy. The end points were 10-year biochemical disease-free survival and distant metastasis-free survival. With an 8-year median follow-up period, the 10-year biochemical disease-free survival in each risk group was significantly improved by dose escalation: 84% (> 75.6 Gy) vs. 70% for low-risk patients (P = 0.04), 76% (> 81 Gy) vs. 57% for intermediate-risk patients (P = 0.0001), and 55% (> 81 Gy) vs. 41% for high-risk patients (P = 0.0001). The 6-month ADT also influenced the biochemical disease-free survival in intermediate-risk and high-risk patients, with 55% vs. 36% for high-risk patients (P < 0.0001). In the multivariate analysis, a dose greater than 81 Gy (P = 0.027) and ADT (P = 0.052) were found to be significant predictive factors for distant metastasis-free survival, but none of these parameters influenced PCa mortality or OS. There were very low rates of grade 3-4 acute or late toxicity (25).

10.3.2.3 Proposed EBRT treatment policy for localised prostate cancer

Low risk. Intensity-modulated radiotherapy with escalated dose and without androgen deprivation therapy is an alternative to brachytherapy (see below).

Intermediate risk. In patients who are suitable for ADT, combined IMRT with short-term ADT (4-6 months) (26,27). In patients who are unsuitable for ADT (e.g., due to comorbidities) or unwilling to accept it (e.g., to preserve their sexual health), IMRT at an escalated dose (80 Gy) or a combination of IMRT and brachytherapy is recommended.

High risk (T1-2 N0-X M0 with either a baseline PSA value > 20 ng/mL and/or a Gleason score of 8-10) plus short-term ADT, suggested by the Boston and 94-08 RTOG trials, did not show any impact on OS in the high-risk cohort. The high risk of relapse outside the irradiated volume makes a combined modality approach mandatory, consisting of dose-escalated IMRT including the pelvic lymph nodes plus long-term ADT. The duration of ADT has to take into account WHO performance status, comorbidities, and the number of poor prognostic factors: cT stage (> T2c), Gleason score 8-10, and PSA > 20 ng/mL.

10.3.3 The role of radiotherapy in locally advanced PCa: T3-4 N0, M0

The incidence of locally advanced PCa has declined as a result of individual and mass screening. Pelvic lymph node irradiation is optional for N0 patients, but the results of radiotherapy alone are very poor (28). The randomised trials discussed above clearly established that, in patients with locally advanced disease who are treated with radiotherapy, the addition of ADT results in better outcomes. However, some clinicians considered that the benefits were due to the earlier use of ADT and questioned the benefits of radiotherapy itself in this context. Three trials have established that in locally advanced disease, radiotherapy is effective and that combined radiotherapy plus ADT is clearly superior to ADT alone.

The National Cancer Institute of Canada (NCIC)/UK Medical Research Council (MRC)/Southwest Oncology Group (SWOG) intergroup PR3/PR07 study included 1,205 patients with T3-4 (n = 1057) or T2, PSA > 40 ng/mL (n = 119), or T2, PSA > 20 ng and Gleason > 8 (n = 25) and N0-X M0 PCa, who were randomly assigned to lifelong ADT (bilateral orchidectomy or LHRH agonist), with or without radiotherapy (65-70 Gy to the prostate, with or without 45 Gy to the pelvic lymph nodes). With a median follow-up period of 6 years, the...
In practice, however, this has the disadvantage that dose distributions from protons are highly contrast, photon beams continue to deposit energy until they leave the body, including an exit dose. Their deposition depth, meaning that critical normal tissues beyond this depth could be effectively spared. In photons, which deposit radiation along their path. There is also a very sharp fall-off for proton beams beyond almost all their radiation dose at the end of the particle's path in tissue (the Bragg peak), in contrast to In theory, proton beams are an attractive alternative to photon-beam radiotherapy for PCa, as they deposit their radiation dose at the end of the particle's path in tissue (the Bragg peak), in contrast to photons, which deposit radiation along their path. There is also a very sharp fall-off for proton beams beyond their deposition depth, meaning that critical normal tissues beyond this depth could be effectively spared. In contrast, photon beams continue to deposit energy until they leave the body, including an exit dose.

In practice, however, this has the disadvantage that dose distributions from protons are highly sensitive to changes in internal anatomy, such as might occur with bladder or rectal filling, and prostate proton therapy is usually delivered with lateral beams. It is also possible that high linear energy transfer (LET)
radiotherapy using protons or carbon ions might offer inherent biological advantages over photons, which have a greater capacity for DNA damage dose for dose.

Only one randomised trial has incorporated proton therapy in one arm: the Loma Linda/Massachusetts General Hospital trial compared standard-dose conformal radiotherapy with dose-escalated radiotherapy using protons for the boost dose (9). This trial cannot, however, be used as evidence for the superiority of proton therapy per se, as its use here could be viewed simply as a sophisticated method of dose escalation. A randomised trial comparing equivalent doses of proton-beam therapy with IMRT is needed in order to compare the efficacy of protons vs. photons; a study of this type is under consideration by the RTOG.

Two recent planning studies comparing conformal proton therapy with IMRT have yielded conflicting results; one study suggested that the two are equivalent in terms of rectal dose sparing, but that IMRT is actually superior in terms of bladder sparing (40); the other study suggested a clearer advantage for protons (41). Further studies are clearly needed. Meanwhile, proton therapy must be regarded as a promising, but experimental, alternative to photon-beam therapy. Theoretically, proton therapy may be associated with a lower risk of secondary cancers in comparison with IMRT because of the lower integral dose of radiation, but there are no data from patients treated for PCa to support this.

Carbon ions offer similar theoretical advantages to those of protons as an alternative to photon-beam therapy. In a phase II study, 175 patients with T1-3, N0-1, M0 PCa were treated with carbon ions at a dosage equivalent to 66 Gy in 20 fractions over 5 weeks (42). The treatment appeared to be well tolerated, with no RTOG grade 3 or 4 bowel or genitourinary toxicity, and an overall 4-year biochemical disease-free rate (BDFR) of 88% (41). As with protons, a randomised trial comparing carbon ions with IMRT and using equivalent doses is required.

10.5 Transperineal brachytherapy

Transperineal brachytherapy is a safe and effective technique. There is a consensus on the following eligibility criteria:

- Stage cT1b-T2a N0, M0.
- A Gleason score ≤ 6 assessed on an adequate number of random biopsies.
- An initial PSA level of ≤ 10 ng/mL.
- ≤ 50% of biopsy cores involved with cancer.
- A prostate volume of < 50 cm³.
- An International Prostatic Symptom Score (IPSS) ≤ 12 (43).

Patients with low-risk PCa are the most suitable candidates for low-dose-rate (LDR) brachytherapy. Further guidelines on the technical aspects of brachytherapy have been published recently and are strongly recommended (44).

In 1983, Holm et al. described the transperineal method with endorectal sonography, in which the patient is positioned in a dorsal decubitus gynaecological position (45). Implantation is undertaken with the patient under general anaesthesia or spinal block, and involves a learning curve for the whole team: the surgeon for delineation of the prostate and needle placement, the physicist for real-time dosimetry, and the radiation oncologist for source loading. The sonography probe introduced into the rectum is fixed in a stable position.

There have been no randomised trials comparing brachytherapy with other curative treatment modalities, and outcomes are based on nonrandomised case series. The results of permanent implants have been reported from different institutions, with a median follow-up ranging from 36 to 120 months (46). The recurrence-free survival after 5 and 10 years has been reported to range from 71% to 93% and from 65% to 85%, respectively (47-54). A significant correlation has been shown between the implanted dose and recurrence rates (55). Patients receiving a D90 of > 140 Gy had a significantly higher biochemical control rate (PSA < 1.0 ng/mL) after 4 years than patients who received less than 140 Gy (92% vs. 68%). There is no benefit from adding neoadjuvant or adjuvant ADT to LDR brachytherapy (46).

Some patients experience significant urinary complications following implantation, such as urinary retention (1.5-22%), post-implantation transurethral resection of the prostate (TURP; required in up to 8.7% of cases), and incontinence (0-19%) (56). A small randomised trial has suggested that prophylactic tamsulosin does not reduce the rates of acute urinary retention, but may improve urinary morbidity (57). This observation requires further study in a larger number of patients. Chronic urinary morbidity can occur in up to 20% of patients, depending on the severity of the symptoms before brachytherapy. Previous TURP for benign prostatic hyperplasia increases the risk of post-implantation incontinence and urinary morbidity.

The incidence of grade III toxicity is less than 5%. Erectile dysfunction develops in about 40% of the patients after 3-5 years. In a recent retrospective analysis of 5,621 men who had undergone LDR brachytherapy (58), the urinary, bowel, and erectile morbidity rates were 33.8%, 21%, and 16.7%, respectively, with invasive procedure rates of 10.3%, 0.8%, and 4%, respectively.

In patients with permanent implants, iodine-125 in granular form is the radioactive element of
reference, while palladium-103 may be used for less differentiated tumours with a high doubling time. The doses delivered to the planning target volume are 144 Gy for iodine-125 and 125 Gy for palladium-103. A Gleason score of 7 is still a "grey area," but patients with a Gleason score of 4 + 3 showed no difference in outcome (59).

A small randomised trial has suggested that using stranded rather than loose seeds is associated with better seed retention and less seed migration, and this should be the standard choice (60).

In cases of intermediate-risk or high-risk localised PCa, brachytherapy in combination with supplemental external irradiation (61) or neoadjuvant hormonal treatment (62) may be considered. The optimum dose of supplemental EBRT is unclear. A randomised trial comparing 44 Gy with 20 Gy of EBRT plus palladium-103 brachytherapy closed early, showing no difference in the biochemical outcomes (63).

Nonpermanent transperineal interstitial prostate brachytherapy using a high-dose-rate iridium-192 stepping source and a remote afterloading technique can be applied with a total dose of 12-20 Gy in two to four fractions, combined with fractionated external radiotherapy of 45 Gy (64). Higher doses of supplemental EBRT than this may best be delivered with IMRT; a report from Memorial Sloan-Kettering indicates that this approach is safe and feasible (65).

Recent data suggest an equivalent outcome in terms of the BDFS in comparison with high-dose EBRT (HD-EBRT) (66). In a retrospective analysis of modern series (67,68), BDFS rates of 85.8%, 80.3%, and 67.8% in men with low-risk, intermediate-risk, and high-risk PCAs, respectively, were reported after a mean follow-up of 9.43 years. Quality-of-life changes are similar with high-dose EBRT and high-dose-rate (HDR) brachytherapy, in terms of diarrhoea and insomnia (69). However, the frequency of erectile dysfunction was significantly increased with HDR brachytherapy (86% vs. 34%). A single randomised trial of EBRT vs. EBRT plus HDR brachytherapy has been reported (70). A total of 220 patients with organ-confined PCAs were randomised to EBRT alone with a dose of 55 Gy in 20 fractions, or EBRT with a dose of 35.75 Gy in 13 fractions, followed by HDR brachytherapy with a dose of 17 Gy in two fractions over 24 hours. In comparison with EBRT alone, the combination of EBRT and HDR brachytherapy showed a significant improvement in the biochemical relapse-free survival (P = 0.03). There were no differences in the rates of late toxicity. Patients randomly assigned to EBRT plus brachytherapy had a significantly better QoL as measured by their Functional Assessment of Cancer Therapy-Prostate (FACT-P) score at 12 weeks. However, a very high, uncommon rate of early recurrences was observed in the EBRT arm alone, even after 2 years, possibly due to the uncommon fractionation used (70). There is still a need to compare dose-escalated EBRT plus hormone therapy, with the same following by a brachytherapy boost, in intermediate-risk and high-risk patients.

For T1-2 N0 M0 disease, the 5-year biochemical failure rates are similar for permanent seed implantation, high-dose (> 72 Gy) external radiation, combination seed/external irradiation, and radical prostatectomy, according to a study of 2991 patients diagnosed with T1-2 consecutive localised PCAs treated between 1990 and 1998 at the Cleveland Clinic Foundation and Memorial Sloan-Kettering Cancer Center, with a minimum follow-up period of 1 year (66).

### 10.6 Late toxicity

Patients must be informed about the potential late genitourinary or gastrointestinal toxicity that may occur, and also about the impact of irradiation on erectile function. Late toxicity was analysed using a dose of 70 Gy in prospective EORTC randomised trial 22863 (1987-1995) (71), in which 90% of patients were diagnosed as having stage T3-4. A total of 377 patients (91%) out of 415 enrolled were evaluable for long-term toxicity, graded according to a modified RTOG scale. Eighty-six patients (22.8%) had grade 2 urinary or intestinal complications or leg oedema, 72 of whom had grade 2 (moderate) toxicity, while 10 had grade 3 (severe) toxicity and four died due to grade 4 (fatal) toxicity. Although four (1%) late treatment-related deaths occurred, the long-term toxicity was limited, with a grade 3 or 4 late complication rate of less than 5% being reported (Table 17). These data can be used as a baseline for comparison with irradiation techniques currently in use, such as 3D-CRT and IMRT.

GI = gastrointestinal; GU = genitourinary.

* Overall toxicity included GU and GI toxicity and leg oedema. As most patients had more than one type of toxicity, the overall toxicity does not result from simple addition.
† Two of the grade 4 patients were irradiated with cobalt-60.

Note: there was no other significant (≥ grade 2) toxicity among patients irradiated with cobalt-60 (n = 15), except for two patients with grade 4 GU (stated above) and only one patient with grade 2 GI toxicity.

Radiotherapy affects erectile function to a lesser degree than surgery, according to retrospective surveys of patients (2). A recent meta-analysis has shown that the 1-year rates of probability for maintaining erectile function were 0.76 after brachytherapy, 0.60 after brachytherapy + external irradiation, 0.55 after external irradiation, 0.34 after nerve-sparing radical prostatectomy, and 0.25 after standard radical prostatectomy.

When studies with more than 2 years of follow-up were selected (i.e., excluding brachytherapy), the rates became 0.60, 0.52, 0.25, and 0.25, respectively, with a greater spread between the radiation techniques and surgical approaches (72).

Recent studies have demonstrated a significantly increased risk of developing secondary malignancies of the rectum and bladder following EBRT (73,74). In a retrospective evaluation of 30,552 and 55,263 men who had undergone either EBRT or RP, the risk of being diagnosed with rectal cancer increased 1.7-fold in comparison with the surgery group (73). Another analysis (74) showed that the relative risk of developing bladder cancer increased by 2.34-fold in comparison with a healthy control population. On the other hand, a re-analysis of SEER data including more than 100,000 patients demonstrated a risk of about 0.16% (i.e., 160 cases per 100,000 patients) of radiation-induced malignant tumours (75).

Corresponding data on late toxicity have also been reported by the Memorial Sloan-Kettering Cancer Center group, from their experience in 1571 patients with T1-T3 disease treated with either 3D-CRT or IMRT at doses of between 66 Gy and 81 Gy, with a median follow-up of 10 years (75). Both acute gastrointestinal and genitourinary toxicity appeared to be predictive for corresponding late toxicity. The overall rate of NCIC/Common Toxicity Criteria (CTC) grade 2 or more gastrointestinal toxicity was 5% with IMRT, in comparison with 13% with 3D-CRT. The incidence of grade 2 or higher late genitourinary toxicity was 20% in patients treated with 81 Gy, in comparison with 12% in patients treated with lower doses. The overall incidence of grade 3 gastrointestinal toxicity was 1%, and grade 3 genitourinary toxicity was 3%. These data suggest that IMRT can successfully protect against late gastrointestinal toxicity, but, interestingly, with dose escalation, genitourinary toxicity may become the predominant type of morbidity (76).

10.6.1 Immediate (adjuvant) postoperative external irradiation after radical prostatectomy

Extracapsular invasion (pT3), Gleason score ≥ 7, and positive surgical margins (R1) are associated with a risk of local recurrence, which can be as high as 50% after 5 years (77,78). Three prospective randomised trials have assessed the role of immediate postoperative radiotherapy (adjuvant radiotherapy, ART). EORTC study 22911 (79), with a target sample size of 1005 patients, compared immediate postoperative radiotherapy (60 Gy) with radiotherapy delayed until local recurrence (70 Gy) in patients classified as having pT3 pN0 with risk.
The most suitable candidates for immediate radiotherapy may be those with multifocal positive surgical margins and a Gleason score > 7. The conclusions of ARO trial 96-02 (n = 385) appear to support those of the EORTC study. After a median follow-up period of 54 months, the radiotherapy group demonstrated a significant improvement in biochemical PFS of 72% vs. 54%, respectively (P = 0.0015). However - of major interest, and in contrast to other studies - randomisation of the patients was carried out after they had achieved an undetectable PSA level following RP (< 0.1 ng/mL), and only pT3 tumours were included. This finding indicates that adjuvant radiotherapy works even in the setting of an undetectable PSA after RP and additional risk factors (81). Conversely, the updated results, with a median follow-up of more than 12 years, of the SWOG 8794 trial, which randomly assigned 425 pT3 patients, showed that adjuvant radiation significantly improved the metastasis-free survival, with a 10-year metastasis-free survival of 71% vs. 61% (median prolongation of 1.8 years, P = 0.016) and a 10-year OS of 74% vs. 66% (median: 1.9 years prolongation; P = 0.023) (82).

Thus, for patients classified as pT3 pN0 with a high risk of local failure after RP due to positive margins and a Gleason score > 7. The conclusions of ARO trial 96-02 (n = 385) appear to support those of the EORTC study. After a median follow-up period of 54 months, the radiotherapy group demonstrated a significant improvement in biochemical PFS of 72% vs. 54%, respectively (P = 0.0015). However - of major interest, and in contrast to other studies - randomisation of the patients was carried out after they had achieved an undetectable PSA level following RP (< 0.1 ng/mL), and only pT3 tumours were included. This finding indicates that adjuvant radiotherapy works even in the setting of an undetectable PSA after RP and additional risk factors (81). Conversely, the updated results, with a median follow-up of more than 12 years, of the SWOG 8794 trial, which randomly assigned 425 pT3 patients, showed that adjuvant radiation significantly improved the metastasis-free survival, with a 10-year metastasis-free survival of 71% vs. 61% (median prolongation of 1.8 years, P = 0.016) and a 10-year OS of 74% vs. 66% (median: 1.9 years prolongation; P = 0.023) (82).

Thus, for patients classified as pT3 pN0 with a high risk of local failure after RP due to positive margins and a Gleason score > 7. The conclusions of ARO trial 96-02 (n = 385) appear to support those of the EORTC study. After a median follow-up period of 54 months, the radiotherapy group demonstrated a significant improvement in biochemical PFS of 72% vs. 54%, respectively (P = 0.0015). However - of major interest, and in contrast to other studies - randomisation of the patients was carried out after they had achieved an undetectable PSA level following RP (< 0.1 ng/mL), and only pT3 tumours were included. This finding indicates that adjuvant radiotherapy works even in the setting of an undetectable PSA after RP and additional risk factors (81). Conversely, the updated results, with a median follow-up of more than 12 years, of the SWOG 8794 trial, which randomly assigned 425 pT3 patients, showed that adjuvant radiation significantly improved the metastasis-free survival, with a 10-year metastasis-free survival of 71% vs. 61% (median prolongation of 1.8 years, P = 0.016) and a 10-year OS of 74% vs. 66% (median: 1.9 years prolongation; P = 0.023) (82).

Thus, for patients classified as pT3 pN0 with a high risk of local failure after RP due to positive margins and a Gleason score > 7. The conclusions of ARO trial 96-02 (n = 385) appear to support those of the EORTC study. After a median follow-up period of 54 months, the radiotherapy group demonstrated a significant improvement in biochemical PFS of 72% vs. 54%, respectively (P = 0.0015). However - of major interest, and in contrast to other studies - randomisation of the patients was carried out after they had achieved an undetectable PSA level following RP (< 0.1 ng/mL), and only pT3 tumours were included. This finding indicates that adjuvant radiotherapy works even in the setting of an undetectable PSA after RP and additional risk factors (81). Conversely, the updated results, with a median follow-up of more than 12 years, of the SWOG 8794 trial, which randomly assigned 425 pT3 patients, showed that adjuvant radiation significantly improved the metastasis-free survival, with a 10-year metastasis-free survival of 71% vs. 61% (median prolongation of 1.8 years, P = 0.016) and a 10-year OS of 74% vs. 66% (median: 1.9 years prolongation; P = 0.023) (82).

Thus, for patients classified as pT3 pN0 with a high risk of local failure after RP due to positive margins and a Gleason score > 7. The conclusions of ARO trial 96-02 (n = 385) appear to support those of the EORTC study. After a median follow-up period of 54 months, the radiotherapy group demonstrated a significant improvement in biochemical PFS of 72% vs. 54%, respectively (P = 0.0015). However - of major interest, and in contrast to other studies - randomisation of the patients was carried out after they had achieved an undetectable PSA level following RP (< 0.1 ng/mL), and only pT3 tumours were included. This finding indicates that adjuvant radiotherapy works even in the setting of an undetectable PSA after RP and additional risk factors (81). However - of major interest, and in contrast to other studies - randomisation of the patients was carried out after they had achieved an undetectable PSA level following RP (< 0.1 ng/mL), and only pT3 tumours were included. This finding indicates that adjuvant radiotherapy works even in the setting of an undetectable PSA after RP and additional risk factors (81). Conversely, the updated results, with a median follow-up of more than 12 years, of the SWOG 8794 trial, which randomly assigned 425 pT3 patients, showed that adjuvant radiation significantly improved the metastasis-free survival, with a 10-year metastasis-free survival of 71% vs. 61% (median prolongation of 1.8 years, P = 0.016) and a 10-year OS of 74% vs. 66% (median: 1.9 years prolongation; P = 0.023) (82).
The role of short-term hormone therapy in combination with radiotherapy is being investigated in the European Organization for Research and Treatment of Cancer (EORTC) 22043 randomised trial.

Decision-making on whether to proceed with adjuvant RT for high risk PCa - pT3-4 pN0 M0 with undetectable PSA - after radical prostatectomy, or to postpone RT as an early salvage procedure in case of biochemical relapse, remains difficult. In everyday practice, the urologist should explain to the patient before radical prostatectomy that adjuvant radiotherapy may be administered if the patient has negative prognostic risk factors. Ultimately, the decision on whether to treat requires a multidisciplinary approach that takes into account the optimal timing of radiotherapy when it is used and provides justification when it is not, and this will help the discussion between the physician and the patient.

### 10.7 Guidelines for definitive radiotherapy

**CRT** = conformal radiotherapy; **IMRT** = intensity-modulated radiotherapy; **ADT** = androgen deprivation therapy; **EBRT** = external beam radiation therapy; **PSA** = prostate specific antigen; **TURP** = transurethral resection of the prostate; **IPSS** = international prostatic symptom score; **RP** = radical prostatectomy; **TURP** = International Prostate Symptom Score.

### 10.8 References

11. EXPERIMENTAL LOCAL TREATMENT OF PROSTATE CANCER

11.1 Background
Besides radical prostatectomy (RP), external beam radiation and/or brachytherapy, cryosurgical ablation of the prostate (CSAP) and high-intensity focused ultrasound (HIFU) have emerged as alternative therapeutic options in patients with clinically localised PCa (1-4).

Although HIFU is still considered to be an experimental treatment, CSAP has been recognised as a true therapeutic alternative according to the guidelines of the American Urological Association. Both HIFU and CSAP have been developed as minimally invasive procedures, which have potentially the same therapeutic efficacy as established surgical and non-surgical options, with reduced therapy-associated morbidity.

11.2 Cryosurgery of the prostate (CSAP)
Cryosurgery uses freezing techniques to induce cell death by:
• dehydration resulting in protein denaturation;
• direct rupture of cellular membranes by ice crystals;
• vascular stasis and microthrombi, resulting in stagnation of the microcirculation with consequent ischaemia;
• apoptosis (1-4).

Freezing of the prostate is ensured by placement of 12-15 17G-cryoneedles under TRUS guidance, placement of thermosensors at the level of the external sphincter and bladder neck, and insertion of a urethral warmer. Two freeze-thaw cycles are used under TRUS guidance, resulting in a temperature of -40°C in the mid-gland and at the neurovascular bundle.

11.2.1 Indication for CSAP
Patients who are ideal candidates for CSAP are those who have organ-confined PCa and those identified as
having minimal tumour extension beyond the prostate (1-3). The prostate should be < 40 mL in size. Prostate glands > 40 mL should be hormonally downsized to avoid any technical difficulty in placing cryoprobes under the pubic arch. PSA serum levels should be < 20 ng/mL, and the biopsy Gleason score should be < 7. It is important that patients with a life expectancy > 10 years should be fully informed that there are no data, or only minimal data, on the long-term outcome for cancer control at 10 and 15 years.

11.2.2 Results of modern cryosurgery for PCa

When comparing treatment modalities, it is important to bear in mind that, in modern RP patients with clinically organ-confined PCa, there is a very low risk (2.4%) of dying from PCa at 10 years after surgery (5). Therapeutic results have improved over time with enhanced techniques, such as gas-driven probes and transperineal probe placement, as used in third-generation cryosurgery (6-11).

An objective assessment of PSA outcome is not easily performed because some institutions use PSA values < 0.1 ng/mL as an indicator of therapeutic success, whereas others use the American Society of Therapeutic Radiology and Oncology (ASTRO) criteria, which requires three consecutive increases in PSA level.

With regard to second-generation CSAP, if a PSA nadir < 0.5 ng/mL is used, biochemical disease-free survival (BDFS) at 5 years is 60% and 36% for low-risk and high-risk patients, respectively (6,7).

Long et al. (6) have performed a retrospective analysis of the multicentre, pooled, CSAP results of 975 patients stratified into three risk groups. Using PSA thresholds of 1.0 ng/mL and < 0.5 ng/mL at a mean follow-up of 24 months, the 5-year actuarial BDFS rate was:

- 76% and 60%, respectively, for the low-risk group;
- 71% and 45%, respectively, for the intermediate-risk group;
- 61% and 36%, respectively, for the high-risk group.

However, according to a recent meta-analysis of 566 cryosurgery-related publications, there were no controlled trials, survival data or validated biochemical surrogate end-points available for analysis (12).

Cryosurgery showed progression-free survival (PFS) of 36-92% (projected 1- to 7-year data), depending on risk groups and the definition of failure. Negative biopsies were seen in 72-87% of cases, but no biopsy data were available for the currently used third-generation cryotherapy machines.

With regard to third-generation cryosurgery, clinical follow-up is short, with a 12-month PSA follow-up carried out in only 110/176 (63%) patients (6-11). Eighty of these (73%) patients still had a PSA nadir < 0.4 ng/mL, whereas 42/65 (64.6%) low-risk patients remained free from biochemical progression using the 0.4 ng/mL cut-off.

Longer follow-up has been reported by Bahn et al. (9), who have analysed the therapeutic results of 590 patients undergoing CSAP for clinically localised and locally advanced PCa. At a PSA cut-off level of < 0.5 ng/mL, the 7-year BDFS for low-, medium- and high-risk groups was 61%, 68% and 61%, respectively.

Nerve-sparing cryosurgery, as reported recently (13), must still be considered an experimental therapeutic option. Nerve-sparing surgery was performed in nine patients with unilateral PCa confirmed on repeated biopsies; CSAP was carried out on the side of the positive biopsy, whereas the negative biopsy side was spared from freezing.

11.2.3 Complications of CSAP for primary treatment of PCa

Erectile dysfunction occurs in about 80% of patients and remains a consistent complication of the CSAP procedure, independent of the generation of the system used. The complication rates described in third generation cryosurgery include tissue sloughing in about 3%, incontinence in 4.4%, pelvic pain in 1.4% and urinary retention in about 2% (6-11). The development of fistula is usually rare, being < 0.2% in modern series. About 5% of all patients require transurethral resection of the prostate (TURP) for subvesical obstruction.

Quality of life and sexuality following CSAP have been investigated in a clinical phase II trial recruiting 75 men (14). Quality-of-life analysis by the prostate-specific FACT-P questionnaire showed that most subscales return to pre-treatment levels by 12 months after CSAP. Furthermore, no significant changes are seen when comparing data at 36 months with those at 12 months. With regard to sexuality, 37% of men were able to have intercourse 3 years after CSAP.

In a recent, prospective, randomised clinical trial, 244 men with newly diagnosed organ-confined PCa were randomised to receive either external beam radiation therapy (EBRT) or to undergo CSAP (15). After a follow-up of 3 years, sexual function was significantly less impaired in the EBRT group.
11.2.4 **Summary conclusions for CSAP**

Patients with low-risk PCa (PSA < 10 ng/mL, < T2a, Gleason score < 6) or intermediate-risk PCa (PSA > 10 ng/mL, or Gleason score > 7, or stage > 2b) represent potential candidates for CSAP.

Prostate size should be < 40 mL at the time of therapy.

Long-term results are lacking, whereas 5-year BDFS rates are inferior to those achieved by RP in low-risk patients. Patients must be informed accordingly.

11.3 **HIFU of the prostate**

HIFU consists of focused ultrasound waves emitted from a transducer, which cause tissue damage by mechanical and thermal effects as well as by cavitation (16). The goal of HIFU is to heat malignant tissues above 65°C so that they are destroyed by coagulative necrosis.

HIFU is performed under general or spinal anaesthesia, with the patient lying in the lateral position. The procedure is time-consuming, with about 10 g prostate tissue treated per hour.

In a 2006 review, 150 papers related to HIFU were identified and evaluated with regard to various oncological and functional outcome parameters (12). No controlled trial was available for analysis, and no survival data were presented. No validated biochemical, surrogate end-point was available for HIFU therapy.

11.3.1 **Results of HIFU in PCa**

As with CSAP, it appears to be difficult to interpret oncological outcome in patients undergoing HIFU because various PSA thresholds are defined, and no international consensus exists on objective response criteria. The results of HIFU are limited, with outcome data from < 1,000 PCa cases published in the literature.

According to the review mentioned above (12), HIFU showed PFS (based on PSA ± biopsy data) of 63-87% (projected 3-5-year data), but median follow-up in the studies ranged from 12-24 months only.

In one of the largest single-centre studies, 227 patients with clinically organ-confined PCa were treated with HIFU, and their outcome data were analysed after a mean follow-up of 27 months (range: 12-121 months) (17). The projected 5-year BDFS was 66%, or only 57% if patients had exhibited a pre-therapeutic PSA value of 4-10 ng/mL. Incontinence and bladder neck stricture decreased over time from 28% and 31% to 9% and 6%, respectively. In one of the studies (18), a significant decrease in pre-treatment PSA serum levels from 12 to 2.4 ng/mL was observed. However, 50% of the 14 patients demonstrated positive prostate biopsies during follow-up. In another study (19), a complete response rate (i.e., PSA < 4 ng/mL) and six negative biopsies were achieved in 56% of the patients.

Thüroff et al. (19) have summarised the efficacy results of a European multicentre study comprising the data of 559 patients with mainly low- and intermediate-risk PCa, and have reported a negative biopsy rate of 87.2% in 288 men with a follow-up of at least 6 months. A PSA nadir after 6 months’ follow-up could be determined in 212 patients, and was 1.8 ng/mL. However, following the initial procedure, it could be demonstrated that the PSA nadir might be reached in 12-18 months.

Blana et al. have reported the results of 146 patients undergoing HIFU with a mean follow-up of 22.5 months (20). The mean PSA level at initiation of therapy was 7.6 ng/mL; the PSA nadir achieved after 3 months was 0.07 ng/mL. However, after 22 months, the median PSA level was 0.15 ng/mL. Of the 137 men available for analysis, 93.4% demonstrated a negative control biopsy. The PSA nadir appeared to be strongly associated with treatment failure (21) (P < 0.001). Patients with a PSA nadir of 0.0-0.2 ng/mL had a treatment failure rate of only 11% compared with 46% in patients with a PSA nadir of 0.21-1.00 ng/mL, and 48% with a PSA nadir of > 1.0 ng/mL. Recently, the group has updated its results, with a total of 163 men treated for clinically organ-confined PCa. Within the 4.8 ± 1.2 years of follow-up, the actuarial DFS rate at 5 years was 66%, with salvage treatment initiated in 12% of patients (22).

In another study, 517 men with organ-confined or locally advanced PCa were treated with HIFU (23). Biochemical failure was defined as the PSA nadir + 2 ng/mL, according to the Phoenix guidelines with regard to radiotherapy. After a median follow-up of 24 months, the BDFS was 72% for the entire cohort. The BDFS in patients with stage T1c, T2a, T2b, T2c and T3 groups at 5 years was 74%, 79%, 72%, 24% and 33%, respectively (P < 0.0001). The BDFS in patients in the low-, intermediate- and high-risk groups at 5 years was 84%, 64% and 45%, respectively (P < 0.0001). The BDFS in patients treated with or without neoadjuvant hormonal therapy at 7 years was 73% and 53% (P < 0.0001), respectively. Postoperative erectile dysfunction was noted in 33 out of 114 (28.9%) patients who were preoperatively potent.

In a recent retrospective study, 137 patients with PCa underwent HIFU (24). After a median follow-up of 36 months, 22% of the patients relapsed according to the Phoenix criteria. The 5-year DFS rate was 78% based on these criteria, and 91%, 81% and 62% in the low-, intermediate- and high-risk group, respectively. Urge incontinence (16 cases) and dysuria (33 cases) occurred after removal of the urethral catheter in 11.8% and 24.1%, respectively.
To evaluate whether the location (apex/midgland/base) of PCa influences the risk of incomplete transrectal HIFU ablation, Bouiter et al. (25) analysed 99 patients who underwent PCa HIFU ablation (Ablatherm; EDAP, Vaulx-en-Velin, France) with a 6-mm safety margin at the apex, and had systematic biopsies at 3-6 months after treatment. After treatment, residual cancer was found in 36 patients (36.4%) and 50 sextants (8.4%); 30 (60%) positive sextants were in the apex, 12 (24%) in the midgland, and eight (16%) in the base. Statistical analysis showed that the mean (95% CI) probability for a sextant to remain positive after HIFU ablation was 8.8% (3.5-20.3%) in the base, 12.7% (5.8-25.9%) in the midgland, and 41.7% (27.2-57.8%) in the apex. When a 6-mm apical safety margin was used, treatment-associated side effects, especially incontinence and erectile dysfunction, were fewer but residual cancer after HIFU ablation was significantly more frequent in the apex.

Komura et al. (26) have analysed the oncological outcome in 144 patients with T1/T2 PCa and a median follow-up of 47 (2-70) months. Thirty-nine percent patients relapsed and approximately 40% developed a clinical or subclinical urethral stricture postoperatively. Most interestingly, the 5-year DFS was significantly better in those with a stricture as compared to those without (78.2% vs. 47.8%, P < 0.001), indicating the need for more aggressive treatment especially at the apex of the prostate.

11.3.2 Complications of HIFU
Urinary retention appears to be one of the most common side effects of HIFU, developing in almost all patients, with the mean interval of catheterisation via a suprapubic tube varying between 12 and 35 days (16-18). Grade I and II urinary stress incontinence occurs in about 12% of patients. Subsequent TURP or bladder neck incision to treat subvesical obstruction is common, and is sometimes even performed at the time of HIFU. Post-operative impotence occurs in 55-70% of patients.

Elterman et al. (27) have treated 95 patients with clinically organ-confined PCa using the Sonablate-500 device, and have evaluated the type and frequency of treatment-associated complications. With a minimum follow-up of 6 months, 17% (7/41) of the men had significant incontinence and 2% developed significant erectile dysfunction. Early and late subvesical obstruction necessitating surgical treatment occurred in 17 (17.9%) and 20 (21.1%) patients, respectively.

11.4 Focal therapy of PCa
During the past two decades, there has been a trend towards earlier diagnosis of PCa due to greater public and professional awareness, leading to the adoption of both formal and informal screening strategies. The effect of this has been to identify men with smaller tumours at an earlier stage, which occupy only 5-10% of the prostate volume, with a greater propensity for unifocal or unilateral disease (28-30).

Most focal therapies to date have been achieved with ablative technologies; cryotherapy, HIFU or photodynamic therapy. So far, three groups have proposed that non-diseased prostate tissue be left untreated in the hope and expectation that genitourinary function might be preserved and the tumour treated adequately (31-33). Although focal therapy is currently not the standard for men with organ-confined PCa, it is the therapeutic approach with the most important future potential.

11.4.1 Pre-therapeutic assessment of patients
The high number of random and systematic errors associated with TRUS-guided biopsy regimens means that this procedure is not sufficiently accurate for selecting candidates for focal therapy. The current standard for characterising men considering focal therapy is transperineal prostate biopsy using a template-guided approach (34,35). When used with a 5-mm sampling frame, this approach can rule in and rule out PCa foci of 0.5 and 0.2 mL volume, with 90% certainty (36). Thus, the exact anatomical localisation of the index lesion - defined as the biologically most aggressive - can be accurately determined.

11.4.2 Patient selection for focal therapy
The primary objective of treatment must be the eradication of measurable and biologically aggressive disease. However, although treatment is usually intended to be one-off, patients should know that further treatment might be necessary in the future.

Based on published data, the following criteria identify possible candidates for currently ongoing trials of focal treatment:
- Candidates for focal therapy should ideally undergo transperineal template mapping biopsies. However, a state-of-the-art multifunctional MRI with TRUS biopsy at expert centres may be acceptable.
- Focal therapy should be limited to patients with a low to moderate risk. The clinical stage of the tumour should be < cT2a and the radiological stage < cT2b.
- Patients with previous prostate surgery should be counselled with caution because no data on
functional and oncological outcomes are available. Patients who have undergone radiation therapy of the prostate are not candidates for focal therapy.

- Patients must be informed that the therapy is still experimental and that there is a possibility of repeat-treatment.

11.5 Summary of experimental therapeutic options to treat clinically localised PCa

**Conclusion**

All other minimally invasive treatment options - such as HIFU microwave and electrosurgery - are still experimental or investigational. For all of these procedures, a longer follow-up is mandatory to assess their true role in the management of PCa.

**Recommendation**

In patients who are unfit for surgery, or with a life expectancy < 10 years CSAP has evolved from an investigational therapy to a possible alternative treatment for PCa.

Focal therapy of PCa is still in its infancy and cannot be recommended as a therapeutic alternative outside clinical trials.

12. HORMONAL THERAPY; RATIONALE AND AVAILABLE DRUGS

12.1 Introduction
In 1941, Huggins and Hodges assessed the effect of surgical castration and oestrogen administration on the progression of metastatic prostate cancer (PCa). They demonstrated for the first time the responsiveness of PCa to androgen deprivation (1,2). Since then, androgen-suppressing strategies have become the mainstay of management of advanced PCa. More recently, there has been a move towards the increasing use of hormonal treatment in younger men with earlier disease (i.e. non-metastatic) or recurrent disease after definitive treatment, either as the primary single-agent therapy or as a part of a multimodality approach (3).

However, even if hormonal treatment effectively palliates the symptoms of advanced disease, there is currently no conclusive evidence to show that it extends life.

12.1.1 Basics of hormonal control of the prostate
Prostate cells are physiologically dependent on androgens to stimulate growth, function and proliferation. Testosterone, although not tumorigenic, is essential for the growth and perpetuation of tumour cells (4). The testes are the source of most androgens, with adrenal biosynthesis providing only 5-10% of androgens (i.e. androstenedione, dihydroepiandrosterone and dihydroepiandrosterone sulphate).

Testosterone secretion is regulated by the hypothalamic-pituitary-gonadal axis. Hypothalamic luteinising hormone-releasing hormone (LHRH) stimulates the anterior pituitary gland to release luteinising hormone (LH) and follicle-stimulating hormone (FSH). Luteinising hormone stimulates the Leydig cells of the testes to secrete testosterone. Within the prostate cell, testosterone is converted to 5-α-dihydrotestosterone (DHT) by the enzyme 5-α-reductase; DHT is an androgenic stimulant about 10 times more powerful than testosterone. Meanwhile, circulating testosterone is peripherally aromatised and converted to oestrogens, which together with circulating androgens, exert a negative feedback control on hypothalamic LH secretion.

If prostate cells are deprived of androgenic stimulation, they undergo apoptosis (programmed cell death). Any treatment that results ultimately in suppression of androgen activity is referred to as androgen deprivation therapy (ADT).

12.1.2 Different types of hormonal therapy
Androgen deprivation can be achieved by either suppressing the secretion of testicular androgens by surgical or medical castration or inhibiting the action of circulating androgens at the level of their receptor in prostate cells using competing compounds known as anti-androgens. In addition, these two methods of androgen deprivation can be combined to achieve what is commonly known as complete (or maximal or total) androgen blockade (CAB).

12.2 Testosterone-lowering therapy (castration)
12.2.1 Castration level
Surgical castration is still considered the ‘gold standard’ for ADT, against which all other treatments are
rated. Removal of the testicular source of androgens leads to a considerable decline in testosterone levels and induces a hypogonadal status, although a very low level of testosterone (known as the 'castration level') persists.

The standard castrate level is < 50 ng/dL. It was defined more than 40 years ago, when testosterone level testing was limited. However, current testing methods using chemiluminescence have found that the mean value of testosterone after surgical castration is 15 ng/dL (1.7 nmol/L) (5). This has led to a revisiting of the current definition of castration, with many authors suggesting a more appropriate level is < 20 ng/dL (0.1 nmol/L).

12.2.2 Bilateral orchiectomy
Bilateral orchiectomy, which is either total or subcapsular (i.e. with preservation of tunica albuginea and epididymis), is a simple and virtually complication-free surgical procedure. It is easily performed under local anaesthesia (6) and is the quickest way to achieve a castration level, usually within less than 12 hours.

The main drawback of orchiectomy is that it may have a negative psychological effect: some men consider it to be an unacceptable assault on their manhood. In addition, it is irreversible and does not allow for intermittent treatment.

12.3 Oestrogens
Oestrogens have several mechanisms of action:
- down-regulation of LHRH secretion;
- androgen inactivation;
- direct suppression of Leydig cell function;
- direct cytotoxicity to the prostate epithelium (in-vitro evidence only) (7).

12.3.1 Diethylstilboesterol (DES)
Diethylstilboesterol (DES) is the most commonly used oestrogen in PCa. Early studies by the Veterans Administration Co-operative Urological Research Group (VACURG) tested oral DES at a dosage of 5 mg/day. However, this dosage was associated with high cardiovascular morbidity and mortality, due to first-pass hepatic metabolism and formation of thrombogenic metabolites. Lower oral doses of 1 mg/day and 3 mg/day were therefore tested and were both found to provide a therapeutic efficacy similar to that of bilateral orchiectomy. However, 3 mg daily of DES was still associated with high cardiotoxicity. Although 1 mg daily of DES resulted in much fewer adverse cardiovascular events than 5 mg daily of DES, the side-effects were still significantly greater than with castration. Recently, there has been renewed interest in using oestrogens (8).

12.3.2 Renewed interest in oestrogens
There are three main reasons for a renewed interest in using oestrogens to treat PCa:
1. Oestrogens suppress testosterone levels and do not seem to lead to bone loss and cognitive decline (9) as do LHRH agonists (LE: 3).
2. In phase II trials for castration refractory PCa (CRPC), oestrogenic compounds (DES, DES-diphosphate) have induced prostate-specific antigen (PSA) response rates as high as 86%.
3. Discovery of a new oestrogen receptor-® (ER-®), possibly involved in prostate tumorigenesis (7).

12.3.3 Strategies to counteract the cardiotoxicity of oestrogen therapy
Two strategies have been used to try and neutralise the cardiotoxicity associated with oestrogen therapy, which is its main disadvantage:
- parenteral route of administration - so avoiding first-pass hepatic metabolism;
- concomitant use of cardiovascular-protective agents.

The Scandinavian Prostatic Cancer Group Study 5 is a large prospective randomized trial which compared a parenteral oestrogen (polyoestradiol phosphate) with CAB (orchiectomy, or an LHRH agonist + flutamide). No difference was observed in disease or overall survival between the treatment groups nor was there any increase in cardiovascular mortality. However, in the oestrogen-treated group, there was a significantly higher incidence of non-fatal adverse cardiovascular events, particularly ischaemic and heart decompensation events (10).

In addition, thromboembolic complications have been observed in trials evaluating the combination of DES, 1 mg/day or 3 mg/ day, with either a low dose of warfarin sodium, 1 mg/day, or a low dose of aspirin, 75-100 mg/day, for the prevention of cardiovascular toxicity (11,12).

12.3.4 Conclusions
Diethylstilboesterol is an effective form of hormonal therapy comparable to that of bilateral orchiectomy (8) (LE:1a). However, there is still concern about the significant cardiovascular side-effects of DES, even at lower
dosages. Further data are needed before oestrogens can be re-admitted into clinical practice as a standard first-line treatment option.

12.4 LHRH agonists

Long-acting LHRH agonists have been used in advanced PCa for more than 15 years and are currently the main forms of ADT (3). They are synthetic analogues of LHRH, generally delivered as depot injections on a 1-, 2-, 3-, 6-monthly, or yearly basis. After the first injection, they stimulate pituitary LHRH receptors, inducing a transient rise in LH and FSH release leading to the ‘testosterone surge’ or ‘flare-up’ phenomenon, which begins 2-3 days later and lasts for about 1 week. No significant difference in efficacy has been observed between the different drugs. But the different drugs have practical differences that need to be considered in everyday practice, including the storage temperature, whether a drug is ready for immediate use or requires reconstitution, and whether a drug is given by subcutaneous or intramuscular injection. It is important to carefully follow the directions for using a particular drug to avoid any misuse.

12.4.1 Achievement of castration levels

Chronic exposure to LHRH agonists eventually results in down-regulation of LHRH-receptors, suppressing pituitary LH and FSH secretion and testosterone production. Testosterone levels decrease to castration levels usually within 2-4 weeks (13). However, about 10% of patients treated with LHRH agonists fail to achieve castration levels (14). This proportion rises to 15% if the castration threshold is defined as 20 ng/dL. A recent meta-analysis evaluating single-therapy ADT for advanced PCa suggested that LHRH agonists have a similar efficacy compared to orchiectomy or DES (8) (LE: 1a) when 2-year survival was the target outcome. This finding raises the question about the clinical impact of changing the definition of the castrate testosterone level from 50 ng/dL to 20 ng/dL. In addition, although only based on indirect comparison, the LHRH agonists seemed equally effective whatever their formulation (8) (LE: 3).

12.4.2 Flare-up phenomenon

Today, LHRH agonists have become the ‘standard of care’ in hormonal therapy. The main concerns are the potentially detrimental effects associated with ‘flare phenomenon’ in advanced disease, namely increased bone pain, acute bladder outlet obstruction, obstructive renal failure, spinal cord compression, and fatal cardiovascular events due to hypercoagulation status.

A recent review (15) concluded that clinical flare needs to be distinguished from the more common biochemical flare (i.e. increasing levels of PSA), and even from asymptomatic radiographic evidence of progression. Patients at risk are usually patients with high-volume, symptomatic, bony disease, which account for only 4-10% of M1 patients. Concomitant therapy with an anti-androgen decreases the incidence of clinical flare, but does not completely suppress the risk. Anti-androgens should be started on the same day as the LHRH analogue and should be continued for a 2-week period. The overall clinical impact of this initial flare is unknown.

Some mini-flares have also been observed with the long-term use of LHRH agonists. The clinical impact is unknown but it has been suggested a mini-flare is associated with a negative impact on overall survival (see Section 15).

12.5 LHRH antagonists

In contrast to LHRH agonists, LHRH antagonists bind immediately and competitively to LHRH receptors in the pituitary gland. The effect is a rapid decrease in LH, FSH and testosterone levels without any flare. This seemed to be a more desirable mechanism of action and has made LHRH antagonists very attractive to use. However, practical shortcomings have limited clinical studies, as many LHRH antagonists have been associated with serious and life-threatening histamine-mediated side-effects and, until recently, no depot formulation was available.

12.5.1 Abarelix

Two published phase III trials compared abarelix, with an LHRH agonist, (16), and with CAB (17), in patients with metastatic or recurrent PCa. Both trials showed no difference in achieving and maintaining castration levels of testosterone and in reducing serum PSA, without any biochemical ‘flare up’ phenomenon in the abarelix arm. Data on survival end-points and long-term safety are not yet available.

The US Food and Drug Administration have recently licensed the clinical use of abarelix in metastatic and symptomatic PCa, for which no other treatment option is available. However, based on prolonged analysis, the FDA has issued a warning about allergic reactions with the long-term use of abarelix, which has resulted in suspension of its further development.
12.5.2 Degarelix
Degarelix is another LHRH antagonist in a monthly subcutaneous formulation. Based on a large, randomized, non-inferiority, dose-finding study (n = 610) the standard dosage of degarelix should be 240 mg the first month, followed by 80 mg monthly injections. More than 95% of patients achieved a castrate level at day 3, which was associated with a quick decline in PSA (as early as day 14). No allergic reaction was observed. The main specific side-effect of degarelix was a painful injection (moderate or mild) reported in 40% of patients, mainly after the first injection. An extended follow-up has been recently published (median 27.5 months), suggesting that degarelix might result in better progression-free survival compared to monthly leuprolelin (18).

12.5.3 Conclusions
Overall, this new family of agents seems appealing, but their advantages over LHRH agonists are far from proven. The use of LHRH antagonists is limited by a monthly formulation. Suppression of the initial flare-up with monotherapy is only clinically relevant in a few, symptomatic, metastatic patients.

12.6 Anti-androgens
These oral compounds are classified according to their chemical structure as:
- steroidal, e.g. cyproterone acetate (CPA), megestrol acetate and medroxyprogesterone acetate;
- non-steroidal or pure, e.g. nilutamide, flutamide and bicalutamide.
Both classes compete with androgens at the receptor level. This is the sole action of non-steroidal anti-androgens. In addition, steroidal anti-androgens have progestational properties leading to a central inhibition. As a consequence, non-steroidal antiandrogens do not lower testosterone levels, which remain normal or, conversely, slightly elevated.

12.6.1 Steroidal anti-androgens
These compounds are synthetic derivatives of hydroxyprogesterone. Since steroidal antiandrogens lower testosterone levels, the main pharmacological side-effects are loss of libido and erectile dysfunction, while gynaecomastia is quite rare. The non-pharmacological side-effects are cardiovascular toxicity (4-40% for CPA) and hepatotoxicity.

12.6.1.1 Cyproterone acetate (CPA)
Cyproterone acetate was the first anti-androgen to be licensed and is the most widely used. However, it is the least studied.

The most effective dose of CPA in monotherapy is still unknown. Although CPA has a relatively long half-life (31-41 hours), it is usually administered in two or three fractionated doses of 100 mg each (19). There has been only one randomized trial (20) comparing CPA with standard medical castration, suggesting a poorer OS compared to LHRH analogs. Although there are other studies in CPA monotherapy, methodological limitations prevent firm conclusions being made from their results about the relative efficacy of CPA and castration. The only comparative study on anti-androgens as monotherapy was recently published by the EORTC, comparing CPA to flutamide in metastatic PCa. No difference in cancer-specific survival and OS at a median follow-up of 8.6 years was observed, although the study was underpowered (21) (LE: 1b).

12.6.1.2 Megestrol acetate and medroxyprogesterone acetate
Very limited information is available on these two compounds. But the overall poor efficacy (22) has prevented them from being recommended for either primary- or second-line hormonal therapy.

12.6.2 Non-steroidal anti-androgens
The use of non-steroidal anti-androgens as monotherapy has been promoted on the basis of improved quality of life (QoL) and compliance compared to castration. They do not suppress testosterone secretion and it is claimed that libido, overall physical performance and bone mineral density (BMD) are preserved (23). Although they have not been directly compared in a monotherapy setting, the severity of pharmacological side-effects, namely gynaecomastia, breast pain and hot flashes, appears similar for the three available non-steroidal anti-androgens. However, there are differences in non-pharmacological side-effects, with bicalutamide showing a more favourable safety and tolerability profile than nilutamide and flutamide (24). All three agents share a common liver toxicity and liver enzymes must be monitored regularly.

12.6.2.1 Nilutamide
There are no comparative trials of nilutamide monotherapy with castration or with other anti-androgens. Non-pharmacological side-effects are visual disturbances (i.e. delayed adaptation to darkness), alcohol intolerance, nausea, hepatotoxicity, and interstitial pneumonitis. Even if exceptional, interstitial pneumonitis is potentially
life-threatening and is specific to nilutamide. Nilutamide is not licensed for monotherapy.

12.6.2.2 Flutamide
Flutamide was the first non-steroidal anti-androgen available for clinical use. Although it has been studied as monotherapy for more than 20 years, there are no dose-finding studies against a currently accepted end-point (e.g. PSA response). Flutamide is a pro-drug, and the half-life of the active metabolite is 5-6 hours, so it must be administered three times daily. The recommended daily dosage is 750 mg (19). The non-pharmacological side-effects of flutamide are diarrhoea and hepatotoxicity (occasionally fatal).

12.6.2.3 Bicalutamide
Dose-finding studies of bicalutamide
The dosage licensed for use in CAB is 50 mg/day, and 150 mg dosage for monotherapy. The non-pharmacological side-effects are mainly gynaecomastia (70%) and breast pain (68%), which may be prevented by anti-oestrogens (25-27), prophylactic radiotherapy (28), or treatment with surgical mastectomy or radiotherapy (29). However, bicalutamide clearly offers bone protection compared with LHRH analogues and probably LHRH antagonists (30,31).

12.7 New compounds
Our knowledge of castration resistant prostate cancer (CRPC) remains incomplete, but is starting to become clearer (5,6). It is thought that castrate resistant disease is mediated through two main overlapping mechanisms, which are androgen-receptor (AR)-independent and AR-dependent (see chapter . . . ). This has led to the development of two new major compounds targeting the androgen axis: abiraterone acetate and lenzaalutamide.

12.7.1 Abiraterone acetate
Abiraterone acetate is a CYP17 inhibitor. It represents an improvement of ketoconazole, which is no longer used or available. By blocking CYP17, abiraterone acetate significantly decreases the intracellular testosterone level by suppressing its synthesis at the adrenal level as inside the cancer cells (intracrine mechanism). In castrate resistant prostate cells, the intracellular androgen level is increased compared to androgen sensitive cells, suggesting an adaptive mechanism, through an increase of androgen biosynthesis (32) enzymes.

12.7.2 Lenzaalutamide
Lenzalutamide (previously known as MDV 3100) is a novel anti-androgen with a higher affinity compared to bicalutamide. It blocks the transfer of ARs to the nucleus so that no agonist-like activity should ever occur. In contrast, currently available drugs still permit the transfer of ARs to the nucleus. The ability of lenzaalutamide to block AR transfer is important because over-expression of the AR has been observed in CRPC.

Both drugs have been developed for use in CRPC after docetaxel has been used. Abiraterone acetate and Lenzaalutamide have shown a significant overall improvement in survival (33,34). Detailed results of both drugs are presented in chapter 20. Both drugs represent an outstanding opportunity for the future treatment of CRPC and confirm that the CRPC status is far from being a hormonal-resistant status.

13. METASTATIC PROSTATE CANCER - HORMONAL THERAPY

13.1 Prognostic factors
The M1 population is heterogeneous (Table 18). Various prognostic factors have been suggested, including general prognostic factors, such as pain, ECOG score, Gleason score or biological information (haemoglobin level, CRP level, alkaline phosphatase), which still need to be confirmed in large trials. The most convincing data come from the large SWOG 8894 trial. Patients who have only nodal metastases or pelvic and axial bone...
metastases have been classified as having minimal disease, compared to those with visceral metastases or appendicular bone metastases, leading to a median overall survival of 58 and 30 months, respectively (1). An updated more precise classification has been published (2), which discriminates patients into three groups according to survival, with a median OS of 54, 30 and 21 months, respectively.

Table 18: Prognostic factors for the heterogeneous M1 population for patients with advanced prostate cancer (2)

13.2 First-line hormonal treatment

Primary androgen deprivation therapy (ADT) is the standard of care, usually with a long-lasting LHRH analogue or antagonist (3). Orchidectomy is still a valid option provided it has been accepted by the patient. There is not yet any convincing data to choose between an LHRH analogue or antagonist, except in patients with an impending spinal cord compression for whom a bilateral orchidectomy or an LHRH-antagonist should be considered first.

13.2.1 Prevention of flare-up

When choosing an LHRH analogue, an initial testosterone flare-up is likely. It is important to prevent a flare in symptomatic patients or in patients for whom a clinical flare might lead to severe complications. However, there is little data to support the long-term impact of preventing a flare-up, as has been suggested (4).

The concomitant administration of an anti-androgen is used to prevent testosterone flare-up. It has been suggested that giving an anti-androgen at the same time as the LHRH analogue may be sufficient to prevent flare-up rather than giving an anti-androgen for some days before treatment is started with an LHRH analogue (5). However, there has been no trial specifically designed to decide the best choice of anti-androgen or modality.

13.3 Combination therapies

13.3.1 Complete androgen blockade (CAB)

Although castration reduces serum testosterone levels by up to 95%, an intraprostatic androgen stimulus is sustained by the conversion of circulating androgens of adrenal origin into DHT within the prostate cells. However, the action of the adrenal androgens can be blocked by adding an anti-androgen to either surgical or pharmacological castration, a concept known as complete (or maximal or total) androgen blockade (CAB).

The many studies comparing CAB with monotherapy have produced conflicting results (6). The largest randomized trial compared surgical castration, with or without flutamide, in 1286 M1b patients. No difference was observed between both groups (1). According to the most recent systematic reviews and meta-analyses, at a follow-up of 5 years, CAB appears to provide a small survival advantage (< 5%) versus monotherapy (7-10) (LE: 1a). However, some of the largest trials included were methodologically flawed (61). It remains debatable whether this small advantage, if any, is useful in everyday clinical practice, as the survival benefit seems limited to patients taking non-steroidal anti-androgens (12) and only appears after 5 years of follow-up.

Gastrointestinal, ophthalmological and haematological side effects are worse with CAB. Although LHRH analogues and non-steroidal anti-androgens have the highest estimated quality-adjusted survival, there is an incremental cost of more than US$1 million per quality-adjusted life-year for CAB over orchidectomy alone.

13.3.2 Non-steroidal antiandrogen (NSAA) monotherapy

13.3.2.1 Nilutamide

There are no comparative trials of nilutamide monotherapy with castration or with other anti-androgens. Nilutamide is not licensed for monotherapy.
13.3.2.2 Flutamide
Early phase II trials suggested the efficacy of flutamide monotherapy in advanced PCa. The main advantage suggested was the preservation of sexual function in up to 80% of patients with no pre-treatment erectile dysfunction. This finding has not been confirmed in the EORTC trial 30892 (13), in which as few as 20% of men treated with flutamide maintained sexual activity for up to 7 years.

In the only published RCT, there was no significant difference in OS for flutamide monotherapy compared to castration in M1b patients with a PSA < 100 ng/mL (14). At a higher PSA, flutamide was inferior. However, the trial was underpowered. Results are still awaited from an ongoing Swedish study, which randomized 700 patients with M1 PCa to flutamide, 250 mg three times daily, or CAB (15).

13.3.2.3 Bicalutamide
Dose-finding studies established that bicalutamide, 150 mg once daily, was chosen for further evaluation, as both primary and adjuvant monotherapy (16). It has been compared to medical or surgical castration in two large prospective RCTs with identical study designs, including a total of 1435 patients with locally advanced M0 or M1 PCa (17). A pooled analysis showed:

- In M1 patients, there was an improvement in OS with castration, although the difference in median survival between the groups was only 6 weeks (17).
- In M0 patients (n = 480), no significant difference was noted in OS (18) based on the Kaplan-Meier test, with median survival being 63.5 months in the bicalutamide arm compared with 69.9 months in the castration one.

In two smaller RCTs, high-dose bicalutamide was compared with CAB. In the first trial (251 patients with predominantly M1 stage), there was no apparent difference in OS (19). In the second trial (220 patients with M0 and M1 stage), there was no difference in OS for well-differentiated tumours (G1) or tumours that were only moderately differentiated (20) (G2) (LE: 1b). However, both studies were underpowered and the first study has not yet been fully published.

High-dose bicalutamide has emerged as an alternative to castration for highly selected, well-informed patients with M1 PCa with a low PSA (21). However, the expected benefit of bicalutamide for QoL compared with castration is far from being proven.

13.3.3 Intermittent versus continuous ADT
For reasons we are beginning to understand, long-term CAB, which stimulates prostate cell apoptosis, fails to eliminate the entire malignant cell population. Thus, after a variable period (averaging 24 months), the tumour inevitably relapses, characterized by a castrate-independent state of growth. Experimental data indicate that castrate-independent progression may begin early after the administration of hormonal therapy, coinciding with the cessation of androgen-induced differentiation of stem cells (22). It has therefore been suggested that stopping androgen deprivation prior to progression of androgen-independent cells would mean any subsequent tumour growth would be solely sustained by the proliferation of androgen-dependent stem cells. The stem cells should therefore be susceptible once again to androgen withdrawal. Thus, intermittent androgen blockade (IAD) would delay the emergence of the androgen-independent clone. It should be noted that this rationale has been developed mainly through models (e.g. the Shionogi model), which may be significantly different to the behaviour of total tumour in men. Other possible benefits of IAD include the preservation of QoL in off-treatment periods and a reduction in the cost of treatment.

A detailed systematic review was recently published (23). It concluded that intermittent IAD was feasible and accepted by patients. However, RCTs are required to clarify the potential survival benefit suggested by animal models.

Overall, nine RCTs are underway, only some of which have published findings. Most of the trials have included a mixed patient population of both locally advanced and metastatic disease, with two trials including only metastatic patients. Results from one of the largest trials (SWOG 9346) (n = 1535), which included only randomized metastatic patients, has been presented, but is not yet published (24). Few fully published trials are available. All the trials that have published results have reported similar findings, except for one trial, allowing the inclusion of abstract-only references.

13.3.3.1 Summary of important trial results in IAD in locally advanced or metastatic PCas
Research in mixed populations of locally advanced and metastatic PCas (25-27):
- There has never been a suggestion of decreased survival using IAD. To date, the largest first fully...
published trial (n = 766) was carried out by the South European Uroncological (SEUG) Group (28) with 30% M1. The primary end-point was time to progression. After a median follow-up of 51 months, there was no difference in either time to progression (HR: 0.81; p = 0.11) or OS (HR: 0.99). The metastatic status and PSA at randomization were associated with specific death rates. No overall QoL benefit was seen, except for more frequent side effects in the CAB-treated group.

- However, there was a clear benefit for improved sexual function in the IAD group versus the CAB group, with 28% sexually active vs 10% at 15 months after randomization, respectively. After a median of 7 years’ follow-up, it should be highlighted that both the IAD treatment arm and the continuous treatment arm showed similar non-significant specific death increases. The second largest study (27) randomized 554 out of 852 patients with either M1 disease (50%) or a locally advanced disease. After a median follow-up of 65 months, no significant difference was observed in the median PFS (34.5 months in the IAD group vs 30.2 months in the CAB group, p = 0.29) in either the total study population or in the N+ or M1 subgroup populations. The median OS was 45 months in both groups.

Research in M1b patients:
- The only published trial on M1b patients included a very small number of patients (n = 341) (29). Again, neither OS nor PFS were different between both arms. However, this trial was clearly underpowered.
- Detailed results are awaited from the SWOG trial 9346, which randomized 1134 men out of 3040 men with stage D2 PCa to intermittent and continuous ADT. This is the largest trial that has been conducted in PCa and findings were first presented at ASCO in 2012. It is a non-inferiority trial, which means that for the first time IAD was presented as being not ‘non inferior’ compared to continuous ADT (median OS 5.1 years for IAD compared to 5.8 years for the continuous treatment arm). Although not yet published, results from this trial have raised the question for the first time of the safety of IAD in metastatic situations (24).
- In 1386 patients relapsing after radiotherapy, the randomized JPR.7 trial has shown no difference in OS after a median follow up of 6.9 years, suggesting that this treatment modality might become the standard for those requiring ADT treatment. The median OS were 8.8 years in the IAD compared to 9.1 years in the continuous treatment arm (HR = 1.02; 0.86-1.21) (30).

IAD regimen of fixed 6-month periods of CAB treatment and surveillance:
An alternative IAD regimen using fixed 6-month periods of CAB treatment and surveillance has been published (31). The results are limited by the small number of patients (n = 129). There was no difference observed in OS, cancer-specific survival or PFS after a mean 44.8 months of follow up.

13.3.3.2 Potential benefits of IAD
Intermittent androgen deprivation has not been shown to be associated with prolonged hormone-sensitive status or an increase in OS. However, this modality is well accepted by patients, urologists and oncologists. Although the QoL benefit is less than expected or absent, except in a few studies (30,32,33), IAD is better tolerated and sometimes benefits sexual functioning (26,28). Other possible long-term benefits, which are not clearly proven, include bone protection (34,35) and/or a protective effect against metabolic syndrome. Testosterone recovery is seen in most studies (23), leading to an intermittent castration (not just an intermittent treatment delivery).

13.3.3.3 Optimal threshold for stopping or resuming ADT
The optimal thresholds at which ADT must be stopped or resumed are empirical (23). The best candidates for IAD have still not been completely defined (23,35), but are probably patients with locally advanced or relapsing disease, provided a perfect response is obtained (see below). Nevertheless, several points are clear (23,36).
- Because IAD is based on intermittent castration, only drugs leading to castration are suitable for use in IAD.
- It is unclear if an LHRH agonist may be used alone, as published experiences are based on CAB. An LHRH antagonist might be a valid alternative, provided clear results are obtained from RCTs.
- The initial (induction) cycle must last between 6 and 9 months, otherwise testosterone recovery is unlikely.
- The treatment is stopped only if patients have fulfilled all the following criteria:
  - well-informed and compliant patient
  - no clinical progression, i.e. a clear PSA response, empirically defined as a PSA < 4 ng/mL in metastatic disease, or 0.5 ng/mL in relapsing disease.
- Strict follow-up must be applied once treatment has stopped, with clinical examination every 3-6 months. The more advanced the disease, the closer should be the follow-up. The PSA level should be measured by the same laboratory to ensure standardization of testing.
In conclusion, IAD is currently widely offered to patients with PCa in various clinical settings and its status should no longer be regarded as investigational (LE: 2). Future publication of the results from the SWOG 9346 may change guidance on the use of IAD in M1B patients.

13.3.4 Immediate versus deferred ADT
There is no discussion regarding symptomatic patients. However, it is still unclear when it is the most appropriate time to introduce hormonal therapy in asymptomatic patients with metastatic PCa. Should hormonal therapy be introduced immediately or deferred until there are signs and symptoms of clinical progression? The controversy has arisen because of the lack of properly conducted RCTs. Published studies have not included enough patients and have been underpowered, with heterogeneity of patient enrolment (i.e. locally advanced, nodal and metastatic stages of disease), and with variation in the hormonal treatments given and in the follow-up schedules and modalities used.

A report by the Agency for Health Care Policy and Research (AHCPR) indicated a possible survival advantage for early ADT in single studies in which hormonal treatment was the primary therapy (37). Furthermore, androgen suppression was shown to be the most cost-effective therapy if it was begun after patients had experienced symptoms from metastatic disease (38). The Cochrane Library review extracted four good-quality RCTs; these were namely VACURG I and II studies, the MRC trial and the ECOG 7887 study, which were all conducted in the pre-PSA era. The studies included patients with advanced PCa, who had received early versus deferred ADT, either as primary therapy or adjuvant to radical prostatectomy (39).

In M1a/b patients only, no improvement in OS was observed, although early ADT significantly reduced disease progression and complication rates due to progression. However, the results were different in locally advanced situations with a relatively small benefit in OS. There was an absolute risk reduction of 5.5% after 10 years (39), while another review reported an OS benefit (+10%) and SS (+20%) (40), especially in combination with a local treatment. In the PSA era, the EORTC 30891 study (41) has clarified the results a small benefit in OS, but not for cancer-specific survival. Furthermore, only young patients with a high PSA are likely to clearly benefit.

Based on a systematic review of the literature, recently published ASCO guidelines on initial hormonal treatment for androgen-sensitive, metastatic, recurrent or progressive PCa concluded that no recommendation can be made about when to start hormonal therapy in advanced asymptomatic PCa, (42). The ESMO guidelines do not make any statement (43).

For asymptomatic metastatic patients, an active clinical surveillance protocol may be an acceptable option in clearly informed patients if survival is the main objective.

The detailed discussion on immediate or deferred ADT combined with surgery or radiation therapy is discussed in Sections 8.3 and 10.3.

13.4 Indications for hormonal therapy
Table 19 lists the indications for hormonal therapy.

<td>1b</td>
</tr>
<tr>
<td>M1 asymptomatic</td>
<td>Immediate castration to defer progression to a symptomatic stage and prevent serious disease progression-related complications</td>
<td>1b</td>
</tr>
</tbody>
</table>
An active clinical surveillance protocol may be an acceptable option in clearly informed patients if survival is the main objective

### Anti-androgens

**Short-term administration**
- To reduce the risk of the ‘flare-up’ phenomenon in patients with advanced metastatic disease who are to receive an LHRH agonist (91,92)

**Long-term administration**
- It may be sufficient to give an anti-androgen for 3 weeks of concomitant use, starting treatment on the same day as LHRH analogue treatment is started, or for up to 7 days before the first LHRH analogue injection

### Intermittent treatment

**Threshold to start and stop ADT**
- The threshold is empirically chosen. However, it should reproduce what has been used in clinical trials. In trials, treatment is usually stopped when the PSA level is < 4 ng/mL (M1) and < 0.5-4 ng/mL (relapsing)

**Drug**
- LHRH analogue + flare-up prevention OR combined treatment

**Population:**
- Metastatic patients: asymptomatic, motivated, with a clear PSA response after the induction period.
- Relapsing after radiotherapy: patients with a clear response after the induction period

14. MANAGEMENT OF PROSTATE CANCER IN OLDER MEN

14.1 Introduction
Prostate cancer is the most prevalent cancer in men, with a median age at diagnosis of 68 years. Two-thirds of prostate cancer-related deaths occur in men aged ≥ 75 years (1). Older men tend to have larger tumours of a higher grade than younger patients (2,3). Treatment decisions for older men should take into consideration the risk of dying from PCa (which depends on the grade and stage of the tumour), potential adverse effects of treatment, and patient preference. Interventions that might decrease health-related quality of life (HRQoL) without prolonging survival should be avoided. Evidence suggests that in both the USA (4) and Europe (5) older patients are under-treated: only a minority of older adults with localised prostate cancer receive curative treatment. However, curative treatment should neither be denied where appropriate, nor limited to androgen deprivation therapy (ADT).

Life expectancy is a major determinant of the potential for benefit from therapy. The International Society of Geriatric Oncology (SIOG) Prostate Cancer Working Group recommends that the decision-making process for treating older men with PCa should be based on a systematic evaluation of health status, most importantly comorbidities, dependence status, and nutritional status (6). These factors influence patient survival and can also affect the ability to tolerate treatment-related side-effects (6).

For localised disease, treatment benefit is usually considered to be seen only beyond 10 years, which leads to a treatment frontier of 75 years. This should be reconsidered, given that Walter (7) has shown that survival probability is linked not only to legal age, but more importantly to overall health status. For example, a healthy 80-year-old senior can expect a median 10.8 years of survival, compared to 6.7 years for a vulnerable, and 3.3 years for a frail senior. At 85 years of age, healthy seniors can expect to survive 8 years. These figures date back 10 years, and are likely to have increased with life expectancy.

Comorbidity is a major predictor of PCa mortality. Tewari et al. demonstrated that comorbidity evaluated by the Charlson index was the strongest predictor of death from causes other than PCa in men with localised PCa treated with RP (8). This was recently confirmed in a cohort of patients from the Surveillance, Epidemiology and End Results (SEER) database, all of whom had treatment-resistant PCa. At 10 years, most men with a Charlson score ≥ 2 died from competing causes, irrespective of age or tumour aggressiveness (9). Currently the Cumulative Illness Score Rating-Geriatrics (CISR-G) is the best available tool for assessing the risk for death unrelated to PCa. Whereas the Charlson index considers only potentially lethal comorbid conditions, the CISR-G also rates nonlethal conditions according to their severity and level of control (10,11).

Level of dependence in daily activities is another factor that influences survival in senior adult patients (12,13). Dependence can be evaluated using the Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADL) scales. The ADL scale rates an ability to accomplish basic activities of daily living, while the IADL scale rates activities that require a higher level of cognition and judgement (for example the ability to manage money or medication, or to use transportation or the telephone).

Malnutrition has also been shown to be associated with an increased mortality rate in senior patients (14). Nutritional status can be estimated by the variation of weight during the previous 3 months:
• good nutritional status < 5% of weight loss;
• risk of malnutrition - weight loss 5-10%;
• severe malnutrition - weight loss > 10%.

Evaluation of comorbidity, dependence and malnutrition is recommended by The SIOG Prostate Cancer Working Group in order to classify patients into one of 4 groups:
1. ‘Fit’ or ‘healthy’ older men should receive the same standard treatment as younger patients.
2. ‘Vulnerable’ patients (i.e. reversible impairment) should receive standard treatment after resolution of any geriatric problems through geriatric interventions.
3. ‘Frail’ patients (i.e. irreversible impairment) should receive an adapted treatment.
4. Patients who are ‘too sick’ with ‘terminal illness’ should receive only symptomatic palliative treatment (6).

“Fit” and “vulnerable” older men with localised PCa in the high-risk group defined by D’Amico et al. (18), with a chance of surviving for more than 10 years are likely to benefit from curative treatment. Older men in the low risk and possibly intermediate risk classification are most likely to benefit from a watchful-waiting approach. The urological approach in older men with PCa should be the same as in younger patients, based on existing recommendations (15-17). Older men with PCa should be managed according to their individual health status which is mainly driven by the severity of associated comorbid conditions and not according to chronological age.

14.2 Treatment-related complications
The risk of short-term postoperative complications appears to be related more to the severity of comorbidities than chronological age. Conversely, the risk of long-term incontinence after RP is more influenced by increasing age than comorbidity (19,20). EBRT has similar outcomes in terms of cancer control and treatment related comorbidities in both older and younger patients, assuming a dose of ≥ 70Gy using intensity modulated radiotherapy (IMRT) or image guided radiotherapy (IGRT). Brachytherapy might be a suitable option in older patients, but survival benefit in older men with low risk disease has not been established. Urinary, bowel, and erectile complications after brachytherapy increase significantly with both increasing age and severity of comorbidities (15). For those with locally advanced disease, a combined modality of EBRT and long term hormonal treatment must be considered. The drawback of ADT in older patients has been discussed earlier (see Chapter 14). Cardiac status should be specially checked if ADT is considered, as it might be associated with increased morbidity, but not mortality. Comorbidity by itself could also be a discriminating factor, as suggested recently in localised high risk patients (21).

In patients with non-metastatic localised PCa unsuitable for curative treatment, immediate ADT should be used only in patients requiring symptom palliation (22,23). In the case of locally advanced T3-T4 disease immediate ADT can be of benefit in patients with PSA > 50ng/mL and PSA doubling time of < 12 months (22,23). ADT is the first-line treatment in hormone-sensitive metastatic PCa. The SIOG Prostate Cancer Working Group recommends evaluation of bone mineral status and prevention of osteoporosis. All men receiving ADT should receive calcium and vitamin D supplementation. The routine use of bisphosphonates to prevent skeletal complications in patients undergoing ADT is not recommended unless there is a documented risk for fracture or castration-resistant PCa with skeletal metastasis (6). However, in a recent randomised trial Denosumab was shown to improve metastases free survival in patients without distant metastases and rising PSA (29.5 months vs 25.2 months, p = 0.0028) and increase time to first bone lesion (33.2 months vs 29.5 months, p = 0.0032) (24).

In metastatic castration-resistant prostate cancer (CRPC), chemotherapy with docetaxel (75 mg/m² every 3 weeks) is the standard for fit and vulnerable older men. The tolerability of the docetaxel 3-weekly regimen has not been specifically studied in frail older men. In a retrospective analysis of 175 patients aged ≥ 75 years treated with docetaxel, patients with a good performance status responded to docetaxel therapy to a similar extent as younger patients. Docetaxel was generally well tolerated. The weekly regimen showed less febrile neutropenia than the 3-weekly regimen but a higher rate of fatigue, resulting in frequent treatment discontinuation (25). The place of weekly docetaxel in metastatic CRPC should be further evaluated. Palliative treatments in CRPC include palliative surgery, radiopharmaceuticals, EBRT, and medical treatments for pain and symptoms.

15. QUALITY OF LIFE OF PATIENTS WITH LOCALISED PROSTATE CANCER

15.1 Introduction
The increase in life expectancy of patients with localised PCa has made the quality of life (QoL) after treatment a key issue for PCa survivors. The term ‘health-related quality of life’ (HRQoL) is typically used to refer to the impact that disease and treatment have on a person’s well-being and physical, emotional and social functioning, including daily functioning (1-4). HRQoL is a patient-centred outcome, which is rated by the patient himself, particularly as physicians often underestimate the impact of disease and treatment on their patients’ lives (5).

In PCa, HRQoL is usually divided into PCa-specific and PCa-general issues. PCa-specific HRQoL refers to the disease-specific outcome of PCa, including urinary, bowel, and sexual functioning. PCa-general HRQoL refers to the generic issues of well-being, including physical, social, emotional, and cognitive functioning, vitality/fatigue, pain, general health status, global QoL and life satisfaction (6).

HRQoL is measured using standardised questionnaires, which collect patient-centric data and provide an objective assessment and perception of both generic and disease-specific domains. Several comprehensive HRQoL questionnaires have undergone validation and have been used to measure early stage PCa outcomes. The most frequently used questionnaires include the EPIC (Expanded Prostate Cancer Index Composite), the Symptom indexes constructed by Clark and Talcott, and the Prostate Module appendix for the EORTC-QLQ C30 (7-9).

Various forms of therapies have different impacts on HRQoL. A comparison of the most common contemporary therapies for localised PCa (radical prostatectomy, brachytherapy, external-beam radiation therapy and active surveillance) is necessary to inform patients about treatment options and to address individual patient preferences for the various possible outcomes. There is still very little objective data about HRQoL for PCa treatment, mainly because of a lack of prospective trials.

15.2 Active surveillance
Although active surveillance avoids treatment-related side effects, it carries an increased risk of psychological distress, which can have significant effects on the patient’s HRQoL. There are certain risk factors for patients who may not do well on active surveillance. These factors include the patient’s perception that the physician is making most of the decision-making, a poor physical health score, a high neuroticism (anxiety) score, and a high PSA value. All these factors were found to have significant positive associations with lower HRQoL scores in multivariate analysis (10). Anxiety and distress did not increase and remained low during the first 9 months of surveillance in men enrolled in the active surveillance PRIAS study (11). Additional research with a longer follow-up is needed to define the significance of negative effects of active surveillance on HRQoL (LE: 1b).

Data from an RCT on anxiety comparing WW and RP (13) found that depression, well-being and psychological status were not significantly different between treatment groups, even if they were systematically...
inferior in the treated group (LE: 1b).

Apart from psychological distress, men left without anticancer treatment may have a higher level of irritative-obstructive urinary symptoms compared to patients treated with RP or RT at 12–36 months of follow-up (14) (LE: 2b).

15.3 Radical prostatectomy
Several trials have shown that RP has a significant negative effect on multiple QoL domains, including a lower sexual function score, lower urinary function and incontinence scores, and a lower physical HRQoL (13,15-17).

In the Prostate Cancer Outcomes Study (PCOS), 8.7% of men at 24 months were bothered by a lack of urinary control and 41.9% reported that sexual function was a moderate-to-big problem in their daily lives (18). Sexual function and interest are the two prostate-specific domains that decline most after surgery and remain most affected after 1 year (19). The recovery of sexual dysfunction and urinary incontinence occurs over 2 to 3 years (20-22). Sanda et al. (15) recently reported that urinary incontinence was at its worst by 2 months after surgery, after which time it improved in most patients. At 1 year after RP, 26% of patients reported that sexual function was a ‘big problem’, while 76% reported that urinary incontinence was a ‘very small’ problem or ‘no problem at all’ (LE: 2a).

Although certain advances have been made that help diminish these side effects, such as nerve-sparing RP or robotic-assisted radical prostatectomy (RALP), their impact on HRQoL remain controversial. Preserving the neurovascular bundles reduces the incidence of impotence (15,23) and can also help to improve urinary function (22,24). Both RALP and open RP have demonstrated comparable functional outcomes and should therefore theoretically have similar HRQoL scores (25). Other general HRQoL domains that may be affected after surgery included pain and energy (18). Several studies have shown that pain and energy worsen immediately post-RP but usually improve by 12 months (20,22,26).

A new methodology for reporting outcomes after RP was proposed recently: the so-called trifecta (27) and pentafecta (28). The new method combines major outcomes, including continence, potency and cancer control (trifecta) and peri-operative complications and positive surgical margins rates (pentafecta). Pentafecta rates reflect post-operative patient expectations and satisfaction more accurately and can be used in counselling patients with clinically localised PCa. The use of trifecta and pentafecta outcomes in post-operative HRQoL assessment needs further validation.

15.4 External-beam radiation therapy (EBRT) and low-dose rate (LDR) brachytherapy
Patients undergoing EBRT and iodine-125 LDR brachytherapy may have urinary, sexual and bowel dysfunction following treatment (29). Both methods can result in irritative voiding symptoms, such as urgency, frequency, and urge incontinence, that negatively affect overall urinary function and HRQoL. The most predominant severe acute toxicity after LDR brachytherapy is urinary retention requiring catheterisation (30). Roeloffzen et al. (30,31) reported that acute urinary retention after LDR brachytherapy occurs in 8–10.2% of patients and has a significant negative impact on patients’ HRQoL up to 6 years after treatment, in terms of both global QoL measures and urinary symptom scores (LE: 3).

A prospective multicentre study showed that the effects of EBRT on urinary symptoms had resolved at 12 months and improved over baseline at 24 months (15). In the same study, patients in the LDR brachytherapy group reported significant detriments in urinary irritation or obstruction and incontinence compared with baseline. Incontinence after LDR brachytherapy was reported by 4-6% of patients at 1-2 years after treatment. Eighteen percent of patients in the LDR brachytherapy group and 11% of those in the EBRT group reported moderate or worse distress from overall urinary symptoms at 1 year (15) (LE: 3).

It has been shown that both EBRT and LDR brachytherapy have a significant impact on the bowel and rectal HRQoL domains (15,32). Bowel/rectal problems appeared to have an overall impact almost as important as that of the urinary domain (33,34). The onset of symptoms occurred during or early after treatment, and sometimes persisted into follow-up. Sanda et al. reported rectal urgency, frequency, pain, fecal incontinence, or haematochezia-caused distress related to bowel function in 9% of patients at 1 year after EBRT or LDR brachytherapy (15). In a retrospective observational study of fecal incontinence in 143 men, who had received LDR brachytherapy for localised PCa, 13.2% (21) of patients at 2 years reported that faecal incontinence was impacting their ability to participate in daily activities (35). A multivariable analysis suggested that bowel and rectal symptoms were less profound after LDR brachytherapy than after EBRT (7) (LE: 2a).

Roeloffzen et al. (31) reported a statistically significant deterioration in HRQoL in patients treated with iodine-125 LDR brachytherapy at 6 years for urinary symptoms, bowel symptoms, pain, physical functioning, and sexual activity. However, most of these changes were not clinically relevant. HRQoL scores returned to approximately baseline values at 1 year and remained stable up to 6 years after treatment. The only clinically relevant changes occurred in emotional functioning and sexual activity. Worse bowel and urinary function may play a stronger role than sexual function in predicting a patient’s overall physical and emotional HRQoL (36). Contemporary treatment refinements, such as 3-D conformal or intensity-modulated radiotherapy (IMRT), may
be able to reduce the impact of EBRT on bowel symptoms, but this has not yet been shown in a multicentre setting.

Dietary intervention had no statistically significant positive impact on gastrointestinal side effects or other aspects of HRQoL in patients undergoing RT (LE: 1b). Sanda et al. showed that adjuvant androgen suppression exacerbated the adverse effects of EBRT or LDR on sexuality and vitality (15). The negative effects of adjuvant hormonal therapy have been shown in some other studies (29,38). The significant worsening of bowel function with the addition of hormones to external radiotherapy was shown at 12 and 24 months after completion of radiotherapy (39).

Among general domains, fatigue was commonly reported following EBRT. However, provided that fatigue was temporary, it did not appear to be emotionally distressing to most men (40,41). Men treated with interstitial LDR brachytherapy appeared to show only slight declines in general HRQoL (42). Physical and functional status declines have been reported in the first few months after implant, but pretreatment levels of function are regained by most men at 1 year after implant (43).

15.5 Comparison of HRQoL between treatment modalities

The limitations of all published studies assessing QoL include the lack of randomisation to treatment and therefore the presence of selection bias, which may influence outcomes. Thus, information regarding comparative outcome relies largely on results from non-randomised observational cohorts. Treatment comparison requires a long follow-up, as measures of QoL may change with time. There are very few trials that are directly comparing different treatment modalities.

Studies addressing general HRQoL issues (general physical function, role function, social function, emotional well-being, body pain, general health, or vitality/energy) have found few differences across treatments for clinically localised disease (6,44). In longitudinal studies, both surgery- and radiotherapy-treated men have reported some declines in role function and vitality/energy shortly after treatment, with surgically treated men reporting the most dysfunction (26,40). However most men recovered function by 1 year after treatment.

The presence of comorbid psychiatric conditions (i.e. prior psychiatric history, alcohol abuse, drug abuse) and the experience of pain after treatment were considered to be certain risk factors for poor general HRQoL in men after treatment for localised prostate cancer (45-47).

The PCOS was the first reported prospective study presenting treatment-specific QoL outcomes for PCa patients at 5 years after initial diagnosis (18). The cohort consisted of men with newly diagnosed localised PCa treated with RP (n = 901) or EBRT (n = 286). At 5 years after diagnosis, overall sexual function declined in both groups to approximately the same level, mostly because of a continuing decline in erectile function among EBRT patients between years 2 and 5. However, erectile dysfunction was more prevalent in the RP group (79.3% vs 63.5%, respectively). Approximately 14-16% of RP and 4% of EBRT patients were incontinent at 5 years. Bowel urgency and painful haemorrhoids were more common in the EBRT group (LE: 2a).

Madalinska et al. evaluated the side effects of RP and EBRT in 278 patients from the ERSPC study at 6 and 12 months following treatment (33). RP patients reported significantly higher incidences of urinary incontinence (39-49%) and erectile dysfunction (80-91%) than radiotherapy patients (6-7% and 41-55%, respectively). Bowel problems (urgency) affected 30-35% of the EBRT group versus 6-7% of the RP group (LE: 2a).

Downs et al. measured the impact of LDR brachytherapy alone on general HRQoL and disease-specific HRQoL compared to patients treated with RP (48). The authors studied 419 men from the CaPSURE database, whose primary treatment was LDR brachytherapy (n = 92) or RP (n = 327). Patients treated with LDR brachytherapy or RP did not differ greatly in general HRQoL after treatment. Both treatment groups showed early functional impairment in most general domains, with scores returning to or approaching baseline in most domains at 18 to 24 months after treatment. Patients treated with LDR brachytherapy had significantly higher urinary function scores at 0 to 6 months after treatment (84.5%) than patients treated with RP (63.3%). Urinary bother scores were not significantly different (67.7% vs 67.4%, respectively). Both treatment groups showed decreases in sexual function that did not return to pretreatment levels (LE: 2a).

A multicentre study that compared all three treatments (RP, EBRT, LDR brachytherapy) in a longitudinal prospective cohort was conducted by Talcott et al. (7). In 417 men, the authors assessed urinary, bowel and sexual function from before primary treatment to 24 months afterwards. Urinary incontinence increased sharply after RP, while bowel problems and urinary irritation-obstruction occurred after EBRT and LDR brachytherapy. Sexual function severely worsened immediately after surgery and then improved, while sexual function continued to decline after both radiation treatments. It has been shown that a surgical patient, who is impotent at 3 or 12 months after surgery, can expect to have a realistic hope of improvement while impotent EBRT patients probably should not. There was no change in urinary function and little change in overall bowel function after 12 months. The data showed that a patient with bowel dysfunction at 12 months after EBRT may expect modest improvement, with diverging trends for individual symptoms. Diarrhoea will continue to subside,
but there will be little change in tenesmus and rectal urgency, and episodes of rectal bleeding will become more prevalent (7) (LE: 2a).

A prospective, multicentre study of 435 patients with a longer follow-up of 36 months was reported by Pardo et al. (49). The study confirmed that there was a long-term change in adverse effects, e.g. an increase in urinary-related adverse effects after EBRT or sexual adverse effects with LDR brachytherapy, which tended to reduce any differences between treatments over time. However, these changes were only slight. In accordance with other reports, the RP-treated group showed greater deterioration in urinary incontinence and sexual function, but improved urinary irritative-obstructive results compared with the LDR brachytherapy group. In patients with urinary irritative-obstructive symptoms at baseline, improvement was observed in 64% of those treated with nerve-sparing RP. Higher bowel worsening was observed in the ERBT group, with 20% of patients reporting bowel symptoms. Relevant differences between treatment groups persisted for up to 3 years of follow-up (49) (LE: 2a).

The American College of Surgeons Oncology Group phase III Surgical Prostatectomy Versus Interstitial Radiation Intervention Trial compared RP and LDR brachytherapy, but was closed after 2 years due to poor accrual. Crook et al. (50) recently reported the HRQoL at a mean of 5.3 years for 168 trial-eligible men, who either chose or were randomly assigned to RP or brachytherapy following a multidisciplinary educational session (50). There were no differences in bowel or hormonal domains. However, men treated with LDR brachytherapy scored slightly better in the urinary QoL domain (91.8 vs 88.1; p = 0.02) and sexual (52.5 vs 39.2; p = 0.001) domain, and in patient satisfaction (93.6 vs 76.9%; p < 0.001). It should be noted that treatment allocation was random in only 19% of cases (LE: 2a).

A population-based study investigated the relationship between presence of urinary, bowel or sexual dysfunction and global QoL in PCa survivors in Norway including men who did not have any active treatment. Men who had undergone RP reported more urinary incontinence (24%) than the other treatment groups, but had the lowest level of moderate or severe urinary irritative-obstructive symptoms. Men who from the ‘no treatment’ group had the highest level of moderate or severe irritative-obstructive urinary symptoms. Men who had undergone RT reported higher levels of irritative intestinal symptoms and faecal leakage compared with the RP group and the no-treatment group. In all treatment groups, poor sexual drive and poor erectile function were common, with men treated with RP reporting the highest prevalence of poor erectile function (89%). The presence of irritative-obstructive urinary symptoms and poor sexual drive were independently associated with low global QoL in multivariate analyses. The use of medication for erectile dysfunction was not significantly associated with global QoL (14) (LE: 2b).

The QoL of a patient’s spouse or partner may also be reduced as a result of their spouse or partner receiving treatment for PCa. In a prospective, multicentre, study of more than 1200 patients and 625 spouses or partners (15), distress associated with the patient’s erectile dysfunction was reported by 44% of partners in the RP group, 22% of those in the EBRT group and 13% of those in the LDR brachytherapy group. After RP, urinary incontinence was observed, but urinary irritation and obstruction improved, particularly in patients with large prostates. Treatment-related symptoms were made worst by obesity, large prostate size, high prostate-specific antigen score and older age (LE: 2a).

Malcolm et al. (51) reported a single-institution study comparing the outcomes of surgery (RP, RALP), LDR brachytherapy and cryosurgical ablation of the prostate (CSAP) with a relatively short follow-up of 24 months (51). The HRQoL of patients treated with LDR brachytherapy and CSAP was associated with higher urinary function and higher bother score compared to open RP and RALP. LDR brachytherapy was associated with a higher sexual function and higher bother score compared to all other treatment modalities. Unfortunately, the study used the UCLA-PCI questionnaire, which lacks items for evaluating irritative urinary symptoms, which are often observed in patients after LDR brachytherapy (48). This may have significantly compromised the results of the HRQoL assessment (LE: 3).

In conclusion, many men treated for clinically localised PCa will experience some post-treatment problems that may impact their daily lives. Each patient therefore has to determine which side effect profile (32) is most acceptable to them when making a decision about treatment.

### 17. FOLLOW-UP: AFTER TREATMENT WITH CURATIVE INTENT

#### 17.1 Definition
Curative treatment is defined as radical prostatectomy or radiotherapy, either by external beam radiation or an interstitial technique, or any combination of these. Alternative treatment options that are not fully established,
such as HIFU, do not have a well-defined, validated PSA-cut-point to define biochemical failure but do generally follow the outlines given below.

17.2 Why follow-up?
The first question to be answered is: ‘If failure after curative treatment is so common, are follow-up efforts worthwhile?’ The answer to this question is definitely ‘yes’. Recurrences will occur in a substantial number of patients who received treatment with intent to cure at various time points after the primary therapy.

The second question to be answered is: ‘What is the reason for follow-up?’ Reasons may vary depending on the treatment given, patient age, co-morbidity and the patient’s own wishes. In general, patients who receive curative therapy may be followed-up for any of the following reasons:

• good responsible patient care;
• possibility of second-line treatment with curative intent;
• possibility of early hormonal therapy after failure;
• as part of a study protocol.

Chapter 18 discusses treatment options after failure of primary therapy.

17.3 How to follow-up?
The procedures indicated at follow-up visits vary depending on the clinical situation. The examinations discussed below are routinely used for the detection of PCa progression or residual disease. The PSA level, and eventually DRE, are the only tests that need to be carried out routinely. A disease-specific history should be mandatory at every follow-up visit and should include psychological aspects, signs of disease progression, and treatment-related complications. The examinations used for the evaluation of treatment-related complications must be individualised and are beyond the scope of these guidelines. The examinations used most often for cancer-related follow-up after curative surgery or radiation treatment are discussed below.

17.3.1 PSA monitoring
The measurement of PSA level is a cornerstone in the follow-up after curative treatment. There is a difference in what can be expected after radical prostatectomy and radiotherapy, but PSA recurrence nearly always precedes clinical recurrence after either treatment, in some cases by many years (1-5). It is recommended that the finding of a single, elevated, serum PSA level should be re-confirmed before second-line therapy is started solely based on the PSA elevation.

17.3.2 Definition of PSA progression
The level of PSA at which to define treatment failure differs between radical prostatectomy cases and radiation treated cases. Following radical retropubic prostatectomy, two consecutive values of 0.2 ng/mL or greater appear to represent an international consensus defining recurrent cancer (6,7). Other authors have argued for an even higher cut-off of 0.4 ng/mL to better define patients with a high risk for clinical progression (5). It has been shown that patients with a PSA level between 0.1 ng/mL and 0.2 ng/mL after radical prostatectomy had neither clinical nor biochemical disease progression (8). Therefore, the use of an ultra-sensitive PSA assay is not justified for routine follow-up after radical prostatectomy (4). If ongoing randomised trials show that early adjuvant treatment after radical prostatectomy (given before PSA reaches > 0.2 ng/mL) improves survival, this issue should be reconsidered.

Following radiation therapy, until recently, the definition of biochemical relapse was three consecutive increases according to the recommendation of ASTRO from 1996 (9). At the 2006 RTOG-ASTRO Consensus conference a new definition of radiation failure was established with as the main aim to establish a better correlation between the definition and clinical outcome. The new definition of radiation failure is a rise of 2 ng/mL above the post-treatment PSA-nadir (lowest value) (10). This definition is applicable for patients treated with or without hormonal therapy.

After HIFU or cryotherapy, a variety of definitions for PSA-relapse have been used (11). Most of these are based on a cut-off of around 1 ng/mL, eventually combined with a negative post-treatment biopsy. As yet, none of these end-points have been validated against clinical progression or survival and therefore it is not possible to give firm recommendations on the definition of biochemical failure.

17.3.3 PSA monitoring after radical prostatectomy
PSA is expected to be undetectable within 6 weeks after a successful radical prostatectomy (12). A persistently elevated PSA level means that PSA-producing tissue remains in the body. In patients treated with radical prostatectomy, this is generally thought to be residual cancer due to either micrometastases that were not detected or undetectable beforehand, or residual disease in the pelvis possibly due to positive surgical margins.
A rapidly increasing PSA level (high PSA velocity, short PSA doubling time) indicates distant metastases, while a later and slowly increasing concentration of PSA is most likely to indicate local disease recurrence. The time to PSA recurrence and tumour differentiation are also important predictive factors distinguishing between local and systemic recurrence (13,14). Both local treatment failure and distant metastases have been shown to occur with undetectable PSA levels. This is very rare and occurs almost only in patients with unfavourable pathology (undifferentiated tumours) (15,16).

This means that, in patients with a relatively favourable pathology (< pT3, pN0, Gleason score < 8), PSA measurement, together with the disease-specific history, could stand as the single test in follow-up after radical prostatectomy.

17.3.4 PSA monitoring after radiation therapy
The PSA level falls slowly after radiotherapy compared with radical prostatectomy. The optimal cut-off value for a favourable PSA nadir after radiotherapy is somewhat controversial. Achieving a PSA nadir of less than 0.5 ng/mL seems to be associated with a favourable outcome (17). The interval before reaching the nadir PSA may be very long and can sometimes take up to 3 years or more. A PSA rising more than 2 ng/mL above the nadir PSA is the current definition of biochemical failure after radiotherapy (10). Also, after radiotherapy, the PSA doubling time has been shown to correlate to the site of recurrence; patients with local recurrence had a doubling time of 13 months compared to 3 months for those with distant failure (18).

17.3.5 Digital rectal examination (DRE)
DRE is performed to assess whether or not there is any sign of local disease recurrence. It is very difficult to interpret the findings of DRE after curative therapy, especially after radiotherapy. A newly detected nodule should raise the suspicion of local disease recurrence.

As mentioned previously, a local disease recurrence after curative treatment is possible without a concomitant rise in PSA level (15,16). However, this has only been proven in patients with unfavourable pathology, i.e. those with undifferentiated tumours. Thus, PSA measurement and DRE comprise the most useful combination of tests as first-line examination in follow-up after radiotherapy or radical prostatectomy, but PSA measurement may well be the only test in cases with favourable pathology (19).

17.3.6 Transrectal ultrasonography (TRUS) and biopsy
TRUS and biopsy have no place in the routine follow-up of asymptomatic patients and nowadays only rarely after biochemical failure. TRUS cannot stand alone as a diagnostic tool, but must usually be combined with biopsy to establish the presence of local disease recurrence. The purpose of the investigation is to confirm a histological diagnosis of local disease recurrence. It is only warranted if the finding of a local recurrence affects the treatment decision (see Section 16 for a more detailed discussion).

17.3.7 Bone scintigraphy
The purpose of bone scintigraphy is to detect skeletal metastases. It is not recommended for the routine follow-up of asymptomatic patients, but may be indicated in individuals with elevated PSA levels for whom the findings will affect the treatment decision. It is also indicated in patients with symptoms arising from the skeleton, since metastatic disease may occur even if PSA is undetectable (15,16).

17.3.8 Computed tomography (CT) or magnetic resonance imaging (MRI)
CT or MRI have no place in the routine follow-up of asymptomatic patients. They may be used selectively in the evaluation after biochemical failure before treatment decisions are made (see Chapter 18).

17.4 When to follow-up?
Most patients who fail treatment for PCa do so early, even if failure only becomes clinically obvious after years. The patient should therefore be followed-up more closely during the first years after treatment when the risk of failure is highest. PSA measurement, disease-specific history and DRE are recommended at the following intervals: 3, 6 and 12 months postoperatively, every 6 months thereafter until 3 years, and then annually. The purpose of the first clinic visit is mainly to detect treatment-related complications and to assist patients in coping with the new situation. Tumour or patient characteristics may allow alterations to this schedule. For example, patients with poorly differentiated and locally advanced tumours or with positive margins may be followed-up more closely than those with a well-differentiated, intracapsular or specimenconfined tumour. Obviously, advanced age or associated co-morbidity may make further follow-up in asymptomatic patients superfluous.

18. FOLLOW-UP AFTER HORMONAL TREATMENT

18.1 Introduction
A large proportion of patients treated with hormonal therapy have either metastatic or locally advanced tumours at diagnosis. This will affect the scheme of follow-up because biochemical failure is often associated with rapid symptomatic progression.

18.2 Purpose of follow-up
The main objectives of following-up these patients are to:
• monitor the response to treatment;
• ensure compliance with treatment;
• detect potential complications of endocrine therapy;
• guide the modalities of palliative symptomatic treatment at the time of CRPC.

It is important to be clear about which complementary investigations are helpful at different stages of the disease to avoid unnecessary patient examinations and excessive economic cost. In addition, strict recommendations for follow-up procedures are only useful if effective therapeutic strategies are available in cases of disease progression. To date, the issue of early versus late initiation of non-hormonal treatment in CRPC has still not been resolved, so follow-up should be performed on an individual basis. Based on current knowledge, it is not possible to formulate level 1 evidence guidelines for follow-up procedures following hormonal therapy.
18.3 Methods of follow-up

18.3.1 Prostate-specific antigen monitoring
Prostate-specific antigen is a good marker for following the course of metastatic PCa. The initial PSA level can be a reflection of the extent of metastatic disease, although some poorly differentiated tumours do not secrete PSA. In recent decades, the PSA value has been used to predict the duration of response to endocrine treatment, based on either the initial pre-treatment value or the PSA decrease during the first 3-6 months. However, the prognostic value of the pre-treatment PSA value is variably assessed in the literature and should not be used alone to predict the duration of treatment response (1).

Treatment response may be assessed using the change in serum PSA level as a surrogate endpoint for survival in patients with newly diagnosed metastatic PCa after hormonal treatment has been initiated. Patients with the lowest absolute value of serum PSA (< 0.2 ng/mL) have been shown to have the best survival compared to patients with a value of 0.2-4.0 ng/mL or > 4.0 ng/mL (2). Similar results have been seen in other studies of locally advanced and metastatic PCa (3-5). The PSA response has been shown to be equally important in patients treated with hormonal therapy, following a rising PSA after treatments with curative intent (radical prostatectomy, radiation therapy). Patients with the best response also had the best survival (6,7).

Despite its usefulness in determining treatment response in individual patients, the role of PSA as a surrogate end-point in clinical trials is more controversial (8). After the initial phase of response to endocrine treatment, patients should be regularly monitored to detect and treat any complications of endocrine escape. Clinical disease progression occurs after a median interval of about 12-18 months of treatment in patients with stage M1 disease. It is well established that regular PSA control in asymptomatic patients allows the earlier detection of biochemical escape because a rise in PSA level usually precedes the onset of clinical symptoms by several months. However, it must be stressed that the PSA level is not the absolute marker of escape and should not be used alone as a follow-up test. Clinical disease progression (usually bone pain) with normal PSA levels has been reported to occur.

18.3.2 Creatinine, haemoglobin and liver function monitoring
Creatinine monitoring has some value because it can detect upper urinary tract obstruction in cases of advanced cancer, which might need to be relieved by, for example, percutaneous nephrostomy or a JJ-stent.

Haemoglobin and liver function tests may suggest disease progression and/or toxicity of hormonal treatment, which can lead to interruption of hormonal treatment (i.e. liver toxicity from non-steroidal antiandrogens). It is important to remember that haemoglobin levels will decrease by about 20% with androgen deprivation (9).

Alkaline phosphatase and its bone-specific isoenzymes have the advantage of not being directly influenced by hormonal therapy compared with PSA. These markers may be used to monitor patients with stage M1b disease. It should be remembered that increases in serum alkaline phosphatase may be due to androgen-induced osteoporosis (10), and in this context, it may be helpful to determine the level of bone-specific alkaline phosphatase.

18.3.3 Bone scan, ultrasound and chest X-ray
In routine practice, asymptomatic patients with a stable PSA level should not undergo a bone scan at regular intervals, because disease progression is more reliably detected by PSA monitoring, which also has a lower cost (11,12).

Moreover, it is also sometimes difficult to interpret bone scans. Thus, in an asymptomatic patient, the therapeutic approach is not modified by the appearance of a new site of uptake or deterioration of pre-existing lesions. Recently, the PCWG2 has clarified the definition of bone scan progression as the appearance of at least two new lesions (13).

Clinical or laboratory suspicion of disease progression indicates the need for a chest X-ray or renal and hepatic ultrasound. Imaging modalities must also be guided by symptoms. However, these examinations are not recommended for routine use in asymptomatic patients. In CRPC disease, follow-up examinations should be individualised with the aim of maintaining the patient’s quality of life.

During long-term ADT, it may be necessary to introduce regular measurement of BMD (LE: 3), based on the initial T-score (14). Bone mineral density should be measured every 2 years if the initial T-score < 1.0, or every year if the T-score is between 1.0 and 2.5, in the absence of associated risk factors (LE: 4). Otherwise, active protective bone treatment should have started at the initiation of ADT (see Chapter 12).

18.4 Testosterone monitoring
Most PCa patients receiving LHRH analogues will achieve serum testosterone values at or below the castration level (< 20 ng/dL). However, about 13-38% of patients fail to achieve this therapeutic goal, while 2-17% of patients do not achieve a serum testosterone level below 50 ng/dL (15-17). Furthermore, up to 24% of men treated with LHRH analogues may experience testosterone surges (testosterone > 50 ng/dL) during long-term
treatment upon re-administration of the agonist drug, which is described as the ‘acute on-chronic effect’ or ‘breakthrough responses’ (16,18).

In view of these findings, the measurement of serum testosterone levels, as well as serum PSA levels, should be considered as part of clinical practice for men on LHRH therapy. The timing of testosterone measurements is not clearly defined. The first evaluation of testosterone level can be recommended at 1 month after initiating LHRH therapy to check the nadir testosterone level achieved before re-administration of the agonist drug. A 6-month testosterone level assessment may be performed to evaluate the effectiveness of treatment and to ensure the castration level is being maintained. If it is not being maintained, switching to another LHRH agent or surgical orchiectomy can be attempted. In patients with a rising PSA and/or clinical signs of progression, serum testosterone must be evaluated in all cases to confirm a castrate-resistant state.

18.5 Monitoring of metabolic complications
Androgen deprivation therapy is beneficial in patients with prostate cancer, but has a greater range of complications than might be expected (see Chapter 12). The most common side-effects of low testosterone levels include hot flashes, lack of libido, erectile dysfunction, gynaecomastia and loss of bone mineral density. In addition, recent studies have suggested that men with low testosterone levels have a higher prevalence of metabolic complications (19), including insulin resistance, arterial stiffness, diabetes and metabolic syndrome. Research has shown that the metabolic syndrome is present in more than 50% of men undergoing long-term ADT, predisposing them to a higher cardiovascular risk (20). Men with metabolic syndrome are almost three times more likely to die of coronary heart disease and other cardiovascular diseases (21), which have now become the most common cause of death in prostate cancer patients, even exceeding prostate cancer mortality (22).

In view of these findings, a cardiology consultation may be beneficial in men with a history of cardiovascular disease and men older than 65 years prior to starting ADT. All patients should be screened for diabetes by checking fasting glucose and HbA1c (at baseline and then every 3 months [LE: 3]). In selected cases, glucose tolerance testing may be required. Men with impaired glucose tolerance and/or diabetes should be referred for an endocrine consultation. Patients on ADT should be given advice on modifying their lifestyle (e.g. diet, exercise, smoking cessation, etc.) and should be treated for any existing conditions, such as diabetes, hyperlipidaemia, and/or hypertension (23,24). The patient’s GP or family physician should probably be more involved in those patients at risk of cardiovascular disease, including monitoring of fasting glucose, lipids profile and blood pressure, which is recommended in all patients receiving long-term ADT. Furthermore, the risk-to-benefit ratio of ADT must be considered in patients with a higher risk of cardiovascular complications, especially if it is possible to delay starting ADT (19,25).

Monitoring bone health is also important, particularly serum levels of Vitamin D and calcium. If needed, supplements should be given so that the patient receives a daily intake of at least 1200 mg/day of calcium and 1000 UI of vitamin D. Preventive therapy with bisphosphonates or denosumab should be considered in patients who have an initial T-score of less than -2.5 on dual-energy X-ray absorptiometry (DEXA), which is the definition of osteoporosis. However, optimal bone monitoring using DEXA is still controversial and should be prospectively evaluated. It is currently suggested that bone monitoring should be performed every 2 years after initiation of castration, provided there are no other risk factors (26), and every year if there are risk factors (27,28).

18.6 When to follow-up
After initiation of hormonal treatment, it is recommended that patients be followed-up at 3 and 6 months. These guidelines must be individualised, and each patient should be told to contact his physician in the event of troublesome symptoms.

18.6.1 Stage M0 patients
If there is a good treatment response, i.e. symptomatic improvement, good psychological coping, good treatment compliance, and a serum PSA level of less than 4 ng/mL, follow-up visits are scheduled every 6 months.

18.6.2 Stage M1 patients
If there is a good treatment response, i.e. good symptomatic improvement, good psychological coping, good treatment compliance, and a serum PSA level of less than 4 ng/mL, follow-up is scheduled every 3 to 6 months.

18.6.3 Castration-refractory PCa
Patients whose disease progresses, or who do not respond according to the criteria mentioned above, warrant an individualised follow-up scheme.

19. TREATMENT OF BIOCHEMICAL FAILURE AFTER TREATMENT WITH CURATIVE INTENT

19.1 Background
Primary curative procedures such as RP and RT are well-established therapeutic options in the management of localised PCa. Technical advances in surgery and RT have both improved the efficacy of treatment and reduced treatment-associated morbidity and toxicity.

Despite these improvements, however, there is still a significant risk of cancer recurrence after therapy. Between 27% and 53% of all patients undergoing RP or RT develop local or distant recurrences, and second-line treatment is required in 16-35% of cases within 10 and 5 years of the initial therapy, respectively (1-6).

19.2 Definitions
19.2.1 Definition of treatment failure
Treatment failure was in the past defined as a recurrence identified during DRE or the development of metastatic disease. Currently, treatment failure is anticipated by a rising PSA level; Pound et al. (7) showed that no patients who were followed up for > 5 years developed a recurrence without a concomitant rise in PSA.

The PSA level that defines treatment failure differs between men who have undergone RP and those who have received RT. Following RRP, there is an international consensus that recurrent cancer may be defined by two consecutive PSA values of > 0.2 ng/mL (6,8). However, the most appropriate definition of biochemical progression after RP is still unclear. A retrospective analysis including 2,782 men who had undergone RP for clinically localised PCa (9) was used to determine the best PSA cut-off point for defining biochemical recurrence (BCR). Once PSA recurrence was detected, there was a subsequent increase in PSA in 49%, 62%, and 72% of patients with PSA levels of 0.2, 0.3, and 0.4 ng/mL, respectively (9). These data indicate that only half of patients with a PSA of 0.2 ng/mL will show further progression, and they can therefore be managed initially by surveillance.

This finding has been confirmed with similar data reported by Stephenson et al. (10), who identified a PSA value of > 0.4 ng/mL, followed by another increase, as the best cut-off level for indicating the development of distant metastases. This level was estimated using definitions obtained from a retrospective review of patients who had developed distant metastases following RP.

After RT, three consecutive increases in PSA following a PSA nadir were considered to provide a reasonable definition of BCR, according to the American Society for Therapeutic Radiology and Oncology (ASTRO) (11). This definition of PSA failure after RT was updated at the RTOG-ASTRO Phoenix Consensus Conference to any PSA increase > 2 ng/mL higher than the PSA nadir value, regardless of the serum concentration of the nadir (12).

A recent study by Kapadia et al. including 710 patients with PCa who were treated with RT with or without ADT showed biochemical failure (BCF) in 21% at a median follow-up of 42 months after EBRT. Biochemical failure was present in 8%, 15%, and 36% of low-risk, intermediate-risk, and high-risk patients, respectively. The authors also found that there was a stronger correlation between a short interval to BCF (defined as failure occurring within 18 months of completing EBRT and/or ADT) and a significantly increased rate of distant metastases, decreased CSS, and decreased OS (13).

19.2.2 Definition of recurrence
A recurrence of PCa can be defined as:
Following RP, PSA values > 0.2 ng/mL, confirmed by two consecutive measurements
Following RT, a PSA value of 2 ng/mL above the nadir after treatment

19.3 Local or systemic relapse

Once a PSA relapse has been diagnosed, it is extremely important to determine whether the recurrence has developed at local or distant sites. About 50% of patients who have undergone RRP will have local disease, while the remainder will have either distant disease alone or distant and local disease (11).

Several important parameters have been suggested in order to differentiate between local and distant relapse:
- Timing of the PSA increase after surgery.
- PSA velocity (PSAV).
- PSA doubling time (PSADT).
- Histopathological stage.
- Gleason score in the prostatectomy specimen.

Prostate-specific antigen increases developing within the first 2 years following surgery are more often associated with distant recurrences (12). It has been shown that a median PSADT of 4.3 months may be associated with distant relapse, whereas a median PSADT of 11.7 months is better predictive of local failure (14). Freedland et al. showed that clinical parameters, PSADT, pathological Gleason score, and time from surgery to BCR are important for stratifying patients into groups with varying levels of risk for prostate cancer-specific mortality (15). In patients who have undergone RP, there is apparently no indication for performing ultrasound-guided biopsies of the vesicourethral anastomosis in order to diagnose local relapse, as this method has low sensitivity and low predictive accuracy in patients with rising PSA levels < 1.0 ng/mL.

In patients who have undergone RT, any continuously rising PSA levels following a nadir after treatment indicate local recurrence, systemic metastatic spread, or a combination of the two (11,15,16). A late and slowly rising PSA level may be a sign of only local failure.

19.3.1 Ultrasensitive PSA

The introduction of ultrasensitive PSA testing has made it possible to screen patients after RP and predict the risk of BCF after surgery at an early stage. Ultrasensitive PSA testing allows more precise measurement of the PSA nadir after radical surgery; patients with a PSA nadir < 0.01 ng/mL developed an early relapse in 4% of cases; by contrast, those with a PSA nadir of 0.04 ng/mL or higher developed an early relapse in 89% of cases (17).

19.3.2 Definition of local and systemic failure

The definitions of local and systemic failure are as follows:
- Following RP, local failure is predicted with an 80% probability by a PSA increase 3 years after surgery, a PSADT > 11 months, a Gleason score < 7, and stage < pT3a pN0, pTx R1.
- Following RP, systemic failure is predicted with > 80% accuracy by a PSA increase at < 1 year after surgery, a PSADT of 4-6 months, a Gleason score of 8-10, and stage ≥ pT3b, pTx pN1.
- After RT, local failure is documented by a positive prostatic biopsy and negative imaging studies such as CT or MRI and bone scintigraphy. Prostatic biopsy after RT is considered necessary only if local procedures with curative intent, such as a salvage radical prostatectomy (SRP), are indicated in an individual patient.

19.4 Evaluation of PSA progression

Before extensive diagnostic work-up is carried out in patients with a PSA relapse following local treatment, men need to be stratified into those who are candidates for salvage therapy and those who are not. Any diagnostic procedures should only be performed if the results will have therapeutic consequences.

In recent years, most patients with PSA progression following initial therapy with curative intent have undergone physical and ultrasound examinations, as well as radiologic investigations or biopsies of the prostatic fossa and the vesicourethral anastomosis to confirm the recurrence suggested by serological studies. The diagnostic yield is very low in patients with asymptomatic PSA-only progression.

As mentioned above, according to Pound et al. (7), not all patients with BCF after RP also develop clinical recurrence. The authors evaluated the follow-up data for 1997 patients after RP, and only 34% of those with BCF subsequently had a clinical recurrence. These data have been confirmed by Boorjian et al. in a study including approximately 2400 patients; only a minority of those with BCF after RP developed a clinically evident recurrence (22.9%) and only few of them died due to PCa (5.8%) (18).
Imaging studies are used to distinguish between local relapse and systemic relapse in order to select the most appropriate treatment modality. Unfortunately, most imaging studies are not sensitive enough to identify the anatomic location of relapsing PCa at PSA levels < 0.5–1.0 ng/mL.

### 19.4.1 Diagnostic procedures for PSA relapse following RP

Traditionally, bone scans and abdominal CT have been used to evaluate increases in the PSA level following primary treatment. Both imaging studies have low sensitivity and specificity, and can be safely omitted from the routine work-up for relapsing patients. Bone scans were examined in 144 patients presenting with PSA recurrences (20): 122 of the patients had undergone RP with no HT, and 22 had received either neoadjuvant or adjuvant ADT. In the first group, the lowest PSA associated with positive scintigraphy findings was 46 ng/mL, while in those who had received HT, the lowest PSA value was 15.47 ng/mL.

The probability of finding a positive bone scan remains < 5% until the serum PSA level reaches at least a value of 40 ng/mL. In other studies, patients with a true positive bone scan had an average PSA level of > 60 ng/mL and a PSAV of 22 ng/mL/year (21,22). Logistic regression analysis showed that PSA and PSAV were good predictors of bone scan results and that PSA was a good predictor of CT scan results. Johnstone et al. (22) found a slight difference between surgically treated patients and those who received RT: 5% and 30% of the bone scans, respectively, were positive.

In summary, bone scintigraphy and abdominal CT scan are of no additional diagnostic value unless PSA serum levels are > 20 ng/mL or PSAV is > 20 ng/mL/year.

The diagnostic accuracy of endorectal MRI (e-MRI) using a 1.5-Tesla machine was investigated in a series of patients with PSA relapse following RP (23). The mean total PSA was 1.23 ± 1.3 ng/mL. The data were compared with standard references for local recurrence, including prostatectomy bed biopsy results, choline PET results, PSA reduction or increase after pelvic RT, and PSA modification during active surveillance. The sensitivity, specificity, positive and negative predictive values, and accuracy were 61.4%, 82.1%, 84.4%, 57.5%, and 69.4%, respectively, for unenhanced e-MRI and 84.1%, 89.3%, 92.5%, 78.1%, and 86.1%, respectively, for enhanced e-MRI. The two methods showed a statistically significant difference in accuracy (chi-squared test = 5.33, $P = 0.02$) and sensitivity (chi-squared test = 9.00, $P = 0.0027$).

Although e-MRI appears to be sensitive and predictive in identifying local recurrences following RP, it does not currently appear capable of becoming a routine imaging modality to be performed in every case, as local vs. systemic relapse may be differentiated at PSA levels < 0.5 ng/mL. At this level of PSA, e-MRI is not sufficiently sensitive or accurate.

Positron-emission tomography has been successfully used in many human cancers for early identification of local or systemic recurrences. In PCa, there are few, even if promising, published data on the clinical efficacy of PET in detecting local recurrences after RP, especially when an increased PSA value is detected (24-28). Choline, as a component of the phosphatidyicholines, is highly increased in PCa and can be easily radiolabeled with either carbon-11 ($^{11}$C-choline) or fluorine-18 ($^{18}$fluorocholine).

Kotzerke et al. (24) reported a potential use of $^{11}$C-acetate PET as a new tool for diagnosing PCa recurrences, with an important impact on management as well. However, Cimitan et al. (25) suggested that in previously treated PCa patients with biochemical recurrences, $^{18}$F-choline PET/CT may not have a significant impact on therapeutic care until PSA increases to > 4 ng/mL, particularly in patients with well or moderately differentiated primary tumors (Gleason score < 7). Choline PET/CT may be helpful in selected patients with higher PSA levels and/or poorly differentiated PCa (Gleason score > 7), to exclude distant metastases when salvage local treatment is intended.

Pelosi et al. (29) reported that the sensitivity of $^{18}$F-choline PET/CT was 20%, 44%, and 80% in patients with PSA levels ≤ 1 ng/mL, 1-5 ng/mL, and > 5 ng/mL, respectively. Husarik et al. (30) evaluated the accuracy of PET/CT for detecting relapses following initial radical treatment for PCa. They confirmed that it is more accurate in patients with PSA levels > 2 ng/mL, regardless of the concomitant use of HT.

Giovacchini et al. (27) reported that PSAV was a predictor of positive $^{11}$C-choline PET/CT and that it can be used to stratify the risk of positive $^{11}$C-choline PET/CT in PCa patients with BCF. The authors concluded that a PSAV rate of > 1 ng/mL/year should be used to increase the rate of positive detection with $^{11}$C-choline PET/CT. The most recent series evaluating the role of $^{11}$C-choline PET/CT in men with biochemical failure after RP showed that metastases were more likely to be identified at higher PSA levels, with a detection rate ranging
from 20% to 36% in patients with PSA levels < 1 ng/mL and increasing to 63-83% in men with PSA levels > 3 ng/mL (31-33).

Recently, Giovacchini et al. (34), evaluating 109 patients with rising PSA levels and negative conventional imaging studies, concluded that $^{11}$C-choline PET/CT may be helpful for re-staging PCa, but it should not be used to guide therapy. The use of $^{11}$C-choline PET/CT in all men with a rising PSA level > 1 ng/mL would result in an 85% incidence of unnecessary examinations, a significant increase in medical costs, and no benefit for the individual patient.

Graute et al. (35) used $^{18}$F PET/CT to try to identify PSA threshold levels, as well as the PSAV, progression rate, and PSADT in relation to the detectability and localisation of recurrent lesions. ROC analysis identified the optimal threshold for distinguishing between PET-positive and PET-negative findings as 1.74 ng/mL (AUC 0.818), resulting in a sensitivity of 82% and a specificity of 74%. In that study, the sensitivity for tumor detection correlated with serum PSA levels, yielding sensitivities increasing from 20% in patients with PSA < 1 to 44% for PSA ≤ 5 ng/mL and 82% for PSA > 5 ng/mL.

Fuccio et al. (26) evaluated consecutive patients with biochemical recurrences (mean PSA value 3.3 ng/mL) after RP. Using $^{11}$C-choline PET/CT, they identified unknown bone lesions in 14.6% of the patients; 33% of these lesions did not reveal any structural change at CT. As previously reported in the literature, the advantage of choline PET/CT may be that it is able to detect bone marrow involvement in PCa patients at an early stage before and after therapy (36,37).

The effects of HT on radiolabeled choline uptake (especially in the skeleton) are of great importance and still under investigation. Giovacchini et al. (38) evaluated the influence of HT on the efficacy of choline PET. Although HT was significantly associated with an increased risk of positive choline PET/CT in the univariate analysis, the effects of ADT were no longer significant in the multivariate analysis.

As recently reported by Picchio et al. (39), routine use of $^{11}$C-choline PET/CT cannot be recommended for PSA values < 1 ng/mL, but a cut-off value for appropriate referral of patients for choline PET/CT imaging has yet to be defined. The accuracy of PET correlates with PSA values, PSADT, and other pathological features. Certainly, a PSADT < 3 months can be regarded as a strong predictor of PET positivity.

Panebianco et al. compared the accuracy of detecting local recurrence of PCa in patients with BCF using proton magnetic resonance spectroscopic imaging ($^{1}$H-MRSI) in comparison with combined dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) techniques with a 3 T magnet vs. $^{18}$F-choline PET/CT. $^{1}$H-MRS-DCEMR combined techniques may be a valid tool for detecting PCa recurrence and may be more accurate than PET/CT for identifying smaller lesions in patients with low biochemical alterations after RRP (0.2-2 ng/mL) (sensitivity 92% vs. 62%; specificity 75% vs. 50%; accuracy 89% vs. 60%) (40).

In summary, the role and diagnostic accuracy of $^{11}$C-choline PET/CT in men with rising PSA following RP depends on the absolute PSA value, PSADT, and PSAV. The higher the PSA level and the faster the PSADT, the better will be the predictive value of this imaging modality. However, even in patients with PSA values > 2 ng/mL and negative imaging studies, $^{11}$C-choline PET/CT is positive in only 28% of patients. It appears that there is an urgent need for well-conducted and histologically controlled trials to explore the potential role of $^{11}$C-choline PET/CT.

### 19.4.2 Diagnostic studies for PSA relapse following radiation therapy

With regard to PSA relapses following RT, routine prostate biopsy should no longer be performed for the evaluation of PSA-only recurrences, according to an ASTRO consensus recommendation (11). However, a prostate biopsy documenting local recurrence represents the main cornerstone in the decision-making process for SRP in patients with rising PSA levels following a nadir after RT (41). It is a general recommendation to wait about 18 months and 3 months after RT or seed implant and cryotherapy or high-intensity focused ultrasound (HIFU), respectively. Patients with rising PSA and a viable cancer on biopsy 2 years after RT have true locally recurrent disease and may be candidates for SRP.

The role of choline PET/CT to detect local or systemic recurrences in men with a PSA relapse following RT is still unclear and based on very few studies (42,43). No conclusive recommendations can therefore be made. The sensitivity and specificity of choline PET/CIT with regard to the detection of lymph node metastases are less reliable, and routine use of $^{11}$C-PET cannot therefore be recommended, especially for PSA values < 1 ng/mL.
The role of e-MRI, MRI spectroscopy, and dynamic contrast-enhanced MRI for the identification of locally recurrent PCa following RT was evaluated in a number of studies (44-46). These studies have demonstrated that locally recurrent PCa can be differentiated from benign nodules due to its low signal intensity on T2-weighted imaging. e-MRI and magnetic resonance spectroscopy were more sensitive than transrectal ultrasonography (TRUS) or TRUS-guided prostate biopsies for detecting viable PCa. e-MRI also contributed important information regarding the presence of extraprostatic extension and seminal vesicle invasion, with a sensitivity of 86% and a specificity of 96%. e-MRI is therefore strongly recommended in the diagnostic work-up of men with a PSA relapse after RT, who may be candidates for secondary local salvage therapy with curative intent.

19.5 Treatment of PSA-only recurrences
The timing and mode of treatment for PSA-only recurrences after RP or RT are still controversial. After RP, the therapeutic options are:

- Radiotherapy to the prostatic bed.
- (Complete) androgen deprivation (CAD, AD).
- Intermittent androgen deprivation (IAD).
- Combination of antiandrogens with 5-alfa-reductase inhibitors.
- Early chemohormonal approaches.

Following RT, the same therapeutic options may apply in relation to PSA recurrences. In addition, SRP, cryotherapy, or brachytherapy may be indicated in carefully selected patients.

19.5.1 Radiotherapy for PSA-only recurrence after RP
Three large randomised controlled trials in adjuvant radiation have been published (47-49). All three reported a BCR-free survival benefit with adjuvant RT of at least 15% at 5 and 10 years.

The largest trial (EORTC-22911, n = 1005) (47) and the smallest trial (ARO-96-02, n = 307) (49) trial were powered to detect a benefit in BCR-free survival, while metastasis-free survival was the primary end-point of the third trial (SWOG-S8794, n = 431) (48). The three trials had similar inclusion criteria. However, the EORTC trial also included pT2 R1 patients, while the other two trials allowed only pT3 cancers with or without positive resection margins. Quite a high proportion of patients in all three trials (63-68%) had positive surgical margins.

It should be noted that the postoperative PSA level before patients were randomly assigned to adjuvant RT differed among the three trials. In the German ARO-96-02 trial, only men with a PSA < 0.1 ng/mL were eligible for randomisation; in the EORTC trial, 11% of men had a PSA level > 0.2 ng/mL prior to randomisation, and 34% in the SWOG trial. Thus, a substantial number of men in the EORTC and SWOG trials received “salvage” radiotherapy (SRT) rather than “adjuvant” RT for a non-normalised PSA. It is therefore of interest that not all of the men in the nonadjuvant arms of the trials were treated with SRT by the time of a biochemical recurrence: delayed RT or SRT to the prostatic fossa was administered in 55% of men with a rising PSA level in the EORTC trial and to 33% of men in the SWOG trial. Thus, the trials were not able to evaluate whether adjuvant therapy was superior to salvage radiation as in the control arm; only half of the men received RT at the time of PSA recurrence.

The authors of the EORTC trial suggested that SRT may be equivalent to adjuvant therapy, provided that the PSA level is < 1 ng/mL (47). However, only the SWOG trial was powered to address the effect of delayed radiation, as it was the only trial with metastasis-free survival as the primary end-point. In the SWOG trial, men in the control arm were less likely to receive SRT (33%). However, it took a median follow-up of over 12 years before metastasis-free survival improved in the adjuvant treatment arm, suggesting that adjuvant therapy may not be helpful in men with a life expectancy of less than 10 years (48,49). Recently, it has been demonstrated that patients in the control group more often had a higher frequency of PCa with Gleason score 8-10 and were more likely not to receive ADT at the time of PSA relapse.

There have been many studies on the use of RT for PSA-only recurrences after RRP. As a result, there is a growing body of parameters for predicting the outcome that may help differentiate between the need for observation, RT, or HT. As confirmed by various studies, the pre-radiotherapy PSA level is critically important for optimal treatment results (41,44,45).

Cotter et al. analysed 4,036 patients with 11.3 years of follow-up who had been treated with RP for PCa, and found that SRT was associated with a significant reduction in all-cause mortality for men with either a PSADT of < 6 months or a PSADT of ≥ 6 months (50).
Siegmund et al. tried to define “what is the best time to treat” patients with biochemical recurrences after RP. They evaluated the biochemical response to SRT, without HT, in 301 patients, with a median follow-up of 30 months. In the multivariate logistic regression analysis evaluating factors influencing an undetectable PSA following SRT, only the pre-SRT PSA level (odds ratio 2.62, P = 0.001) and infiltration of the seminal vesicles (odds ratio 2.53, P = 0.02) were found to be independent predictive factors. The authors found that patients with a PSA level < 0.28 ng/mL before SRT had a better outcome than those with higher PSA levels and that they may have a chance of a long-term durable response without further treatment (51). Similarly, a major role for early SRT was reconfirmed by a systematic review by Ohri et al., who demonstrated that the biochemical recurrence-free survival (BCR-FS) increased along with the SRT dosage by 2.5% per Gy and decreased along with the pre-SRT PSA by 18.3% per ng/mL (P < 0.001) (52).

ASTRO has published a consensus paper recommending a dosage of at least 64 Gy when the PSA level is < 1.5 ng/mL after RRP (11).

Stephenson et al. evaluated prognostic models for predicting the outcome of SRT in a cohort of 1603 men with PSA progression after RP who underwent surgery in 17 North American tertiary referral centres. They identified a significant relationship between the PSA value at the time of RT and the therapeutic outcomes. Specifically, the 6-year BCR-FS estimates were 48% in men with PSA < 0.5 ng/mL and only 40%, 28%, and 18% in men with PSA levels of 0.51-1.0 ng/mL, 1.01-1.50 ng/mL, and > 1.50 ng/mL, respectively (53).

In the SWOG and EORTC nonadjuvant radiotherapy arms, the median intervals to SRT were 2.0 and 2.2 years, respectively. In the SWOG 8974 study, 23% of men had a PSA level > 1.5 ng/mL prior to SRT. In a subanalysis of the SWOG 8,974 trial, Swanson et al. (54) showed that men in all categories of post-prostatectomy PSA levels (< 0.2, 0.2-1.0, > 1.0 ng/mL) had improved metastasis-free survival after SRT. However, the therapeutic benefit was most evident in the presence of minimal PSA serum levels. These data suggest that, although less effective, SRT may help improve the metastasis-free survival.

In a multi-institutional, matched-control analysis of adjuvant and salvage postoperative RT for pT3-4 N0 PCa, Trabulsi et al. (55) demonstrated a BCR-FS advantage in favor of adjuvant RT vs. SRT. Interestingly, in a multivariable Cox regression analysis, adjuvant RT vs. SRT was not an independent predictor of metastatic PFS, after correction for adverse clinical and pathological factors.

Data have become available on overall survival and SRT. In a group of men with a median follow-up of 9 years after radical prostatectomy, the benefit of SRT for PCa-specific mortality was seen particularly in men with a PSADT of less than 6 months who had received SRT to the prostate fossa within 2 years after a rise in PSA (56). This suggests that local disease control may prolong the prostatic CSS in men formerly thought to be at risk for systemic disease progression and less likely to benefit from (salvage) RT.

Men with slowly progressing disease, although they are still at risk for systemic progression, may not benefit from SRT as they have a low risk for developing fatal PCa. Longer follow-up periods are certainly needed in order to answer this question.

19.5.1.1 Dose, target volume, toxicity
The three randomised trials on adjuvant RT all used dosages < 66 Gy, which is currently the most frequently used dosage for adjuvant and salvage RT. However, it is important to note that, as with dose escalation studies in primary radiation for PCa, an increased dose in the salvage setting may improve the biochemical response without worsening local toxicity (57,58). Dosages of up to 70 Gy have shown better BCR-free rates at higher dosages, with 66.8 Gy RT found to be the dosage required for 50% BCR-free survival. Even higher doses may be considered, particularly when using improved imaging techniques, such as fiducial markers (59). The finding that 9% of men develop a local recurrence after adjuvant radiation of 60 Gy provides support for an increase in the dosage and target volume (54).

Target volume delineation has been found to vary by up to 65% between different radiotherapists administering adjuvant or salvage radiation to the prostatic fossa (60-62). It is therefore important not to overlook local toxicity. In the EORTC 22911 study, 3.1% of men had to interrupt adjuvant RT because of local symptoms, mainly diarrhoea. Although grade 3 or 4 toxicity is rare for either adjuvant or SRT to the prostatic fossa, it was almost doubled in the adjuvant arm of the EORTC 22911 study (2.6% vs 4.2%) and the SWOG S8794 study, particularly with regard to urethral strictures (relative risk 9) and incontinence (relative risk 2.3).

19.5.2 Hormonal therapy
Systemic failure following RP is predicted with > 80% accuracy by a PSA relapse < 1 year, a PSADT of 4-6 months, Gleason score 8-10, and stage pT3b, pTx pN1. There is some evidence that early HT may help delay progression and possibly achieve a survival benefit (63,64).
19.5.2.1 Adjuvant hormonal therapy after RP

In the absence of randomised controlled trials for postoperative PSA recurrence, it is necessary to rely on retrospective data or to extrapolate data from other clinical settings, such as men with metastatic disease or locally advanced nonmetastatic disease. It is uncertain whether or not such data are relevant to men with rising postoperative PSA levels.

Two randomised studies have compared immediate HT (after diagnosis) with deferred HT (on progression) in patients with PCa. The Medical Research Council study in locally advanced or asymptomatic metastatic PCa and the EORTC study in newly diagnosed PCa (T0-4 N0 M0) illustrate that, although immediate HT after diagnosis may delay disease progression in men with PCa, this does not necessarily result in an improved CSS (65,66).

A survival advantage for immediate (adjuvant) ADT after RP has only been confirmed in patients with positive lymph node PCa in a single randomised study (63,64).

Mydin et al. concluded that early salvage HT based on PSA < 10 ng/mL and absent distant metastases improved the survival in patients with PCa after the failure of initial treatment with neoadjuvant HT plus RT (67).

Adjuvant bicalutamide (150 mg) was able to decrease progression in men with locally advanced PCa, but did not result in an OS benefit (68). Several retrospective analyses from the Mayo Clinic have shown that adjuvant HT after RP had a positive effect on the time to progression and cancer death in pT3b and N+ patients (69-71). However, large series from the Mayo Clinic with a median follow-up of 10.3 years show that adjuvant HT in surgically managed N+ patients decreased the risk of BCF and local recurrence, but did not have a significant impact on systemic progression or CSS (72). Another retrospective study with a median follow-up period of 5.2 years showed that immediate and delayed HT (at PSA recurrence) in surgically managed N+ patients provided similar outcomes (73).

An observational study has shown that deferred vs. immediate ADT in N+ men after RP may not significantly compromise survival. There was no statistically significant difference in the OS between the adjuvant ADT group and the non-ADT group. These results need to be validated in a prospective study (74).

19.5.2.2 Postoperative hormonal therapy for PSA-only recurrence

Androgen deprivation therapy

Although patients with postoperative PSA recurrences often undergo ADT before there is any evidence of metastatic disease, the benefit of this approach is uncertain. A retrospective study including 1,352 patients with postoperative PSA recurrence showed no significant difference in the time to clinical metastases with early ADT (after PSA recurrence, but before clinical metastases) vs. delayed ADT (at the time of clinical metastases). However, after risk stratification, it was found that early ADT was able to delay the time to clinical metastases in high-risk patients with a Gleason score > 7 and/or a PSADT < 12 months. ADT had no overall impact on the PCa-specific mortality (75).

It has been shown (76) that adjuvant ADT (within 90 days of surgery) slightly improved the CSS and systemic PFS after RP in a large group of high-risk PCa patients. The survival advantage was lost when ADT was administered later in the disease process, at the time of PSA recurrence or systemic progression. It should be emphasised that there was no advantage with regard to OS (83% in both groups) and that the differences in the CSS and systemic PFS were only 3% and 5%, respectively. In a retrospective study including 422 patients with postoperative PSA recurrences, 123 developed distant metastasis, of whom 91 patients with complete data received deferred ADT at the time of documented metastasis after RP. It was concluded that when closely followed up after PSA recurrence, patients may have an excellent response to deferred ADT and a long survival period, with a median failure time of 169 months from RP to death (77). These three studies are limited by their retrospective design and in assessing the side effects of long-term ADT. They do not allow any definitive conclusions to be drawn on the use of early HT in clinical practice.

Antiandrogens

Although gynecomastia and breast tenderness were the most predominant side effects of treatment for organ-confined and locally advanced PCa, the incidence of hot flushes, loss of libido, and impotence was significantly lower than expected for luteinising hormone-releasing hormone (LHRH) agonists and complete androgen deprivation (CAD) (78).

However, the OS did not differ between the groups (79). Low-dose flutamide (250 mg daily) is currently being investigated in men with PSA recurrences.
Intermittent androgen deprivation

Intermittent androgen deprivation (IAD) has been examined as a potential alternative to CAD in order to:

• Delay the time to androgen independence and hormone-refractory disease.
• Minimise side effects.
• Reduce the costs of prolonged therapies.

There are no long-term data from large-scale randomised controlled trials that can confirm the superiority of IAD over CAD for survival. Limited information suggests that IAD may result in a slight reduction of adverse effects (80). However, in the setting of PSA-only recurrences, there are no prospective randomised trials and no clinical studies with sufficient data on long-term efficacy to justify the routine clinical application of IAD, despite its potential benefits.

In the series in which PSA-only recurrences were treated with IAD (81-84), PSA threshold levels at study entry varied significantly, as did the PSA level at discontinuation of HT. Crook et al. randomly assigned 690 patients to IAD and 696 to CAD. There were no significant between-group differences with regard to adverse events; in the IAD group, full testosterone recovery occurred in 35% of patients, and testosterone recovery to the trial-entry threshold occurred in 79%. Intermittent androgen deprivation provided potential benefits with respect to physical function, fatigue, urinary problems, hot flushes, libido, and erectile function (85).

Minimal androgen blockade

In some studies, finasteride and flutamide have been combined for the management of PSA-only recurrences, since the two agents work additively by blocking the intraprostatic conversion of testosterone to dihydrotestosterone (DHT) and blocking the intracytoplasmic DHT receptor (86-88). In the latest report (87), including 73 patients, administration of finasteride (10 mg/day) and low-dose flutamide (250 mg/day) resulted in a mean PSA nadir of 1.35 ng/mL within 6 months. However, only 62% of the patients studied reached a PSA nadir of < 0.2 ng/mL.

After a mean follow-up period of 15 months, none of the patients had progressed to traditional HT. However, longer follow-up of a larger patient cohort is needed, and randomised phase III trials using modern antiandrogens with fewer gastrointestinal and hepatic side effects are mandatory.

Hormonal therapy after RP combined with radiotherapy and/or chemotherapy

The addition of HT to SRT (n = 78) was not associated with any additional increase in the CSS (88). A phase II trial including 74 patients with postoperative PSA recurrences showed that combined treatment with SRT plus 2 years of CAD (castration + oral antiandrogen) had relatively minor long-term effects on quality of life (89). However, more efficacy data are needed and the potential increase in side effects should be considered when combining therapies. Results are eagerly awaited from a recently completed randomised controlled phase III study from the Radiation Therapy Oncology Group (RTOG-9061) comparing RT + placebo vs. a combination of RT + bicalutamide (150 mg daily) in the postoperative setting.

Radiotherapy and ADT in combination after local surgery are being investigated in a recently started, large, randomised, controlled study sponsored by the Medical Research Council. The study is addressing the timing of RT (adjuvant vs early salvage) and the duration of HT (none vs. short-term vs. long-term) used together with postoperative RT. The primary outcome measure will be CSS. Secondary outcome measures will include OS, ADT administered outside the protocol, and reported treatment toxicity. The study is also aiming to assess the long-term effect of RT after RP on sexual, urinary, and bowel function, and the long-term effect of ADT on sexual function and the overall quality of life (90).

Currently, it seems there is no indication for chemotherapy in patients with PSA-recurrence only. Chemotherapy should be considered as a treatment option for patients with castration-resistant PCa, but when a cytotoxic regimen should be initiated is still a matter of controversy (91).

19.5.3 Observation

Observation until the development of clinically evident metastatic disease may represent a viable option for patients with a Gleason score < 7, PSA recurrence > 2 years after surgery, and a PSADT of > 10 months. In these patients, the median actuarial time to the development of metastasis will be 8 years and the median time from metastasis to death will be a further 5 years (7).

19.6 Management of PSA failures after radiation therapy

In a review of data from the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE), including 2336 patients with PCa, Grossfeld et al. (92) demonstrated that 92% of patients who had initially been treated with RT received ADT for secondary treatment of PSA progression, with no salvage procedures. The mean time interval from biochemical to clinical progression is approximately 3 years. Therapeutic options in these patients are ADT or local procedures such as salvage RP, cryotherapy, and interstitial RT (41,93-101). Salvage radiotherapy has not gained widespread acceptance because of the morbidity associated with it - namely, urinary incontinence (UI), local recurrences, and rectal injuries. However, in well-selected patients, the procedure may result in long-term disease-free survival.

19.6.1 Salvage radical prostatectomy

Previously, most series reporting on SRP have included patients treated in the pre-PSA era without modern radiotherapeutic techniques, when local recurrences were usually detected at a late stage. Complications associated with the procedure were therefore quite high, with up to 65% of patients suffering from treatment-related morbidity. Up to 60% of patients who underwent SRP had to undergo anterior or total exenteration for locally extensive disease, associated with a high rate of local recurrences and a mean time to progression of 1.3 years.

Recent reports analysing patients who were operated on during the past decade have described much more optimistic outcomes after SRP. In a recent systematic review of the literature, Chade et al. showed that SRP allowed 5-year and 10-year biochemical recurrence-free survival (BCR-FS) estimates ranging from 47% to 82% and from 28% to 53%, respectively. The 10-year cancer-specific and OS rates ranged from 70% to 83% and from 54 to 89%, respectively. The pre-SRP PSA value and prostate biopsy Gleason score were the strongest predictors of the presence of organ-confined disease, progression, and CSS. The authors also highlighted that the associated surgical morbidities were acceptable in the hands of experienced surgeons (102).

In a multicentre series, at 10 years after SRP, Chade et al. reported a BCR-FS of 37%, a metastasis-free survival of 77%, and a CSS of 83%. In a preoperative multivariate analysis in the study, the pre-SRP PSA and the Gleason score at post-radiotherapy prostate biopsy were found to be predictive of biochemical recurrence (103).

In the series reported by Garzotto and Wajsman (97), 24 patients underwent radical cystoprostatectomy or RP with neoadjuvant ADT. Neoadjuvant ADT was associated with a lower rate of positive surgical margins (21%) in comparison with patients in whom ADT failed, who had a positive surgical margin rate of 80%. The authors showed that the disease-specific survival correlated strongly with surgical margin status. After a mean follow-up period of 5 years, the disease-specific survival rates were 95% and 44% for those with negative and positive surgical margins, respectively. Vaidya and Soloway reported a low rate of complications, good postoperative continence, and only one biochemical recurrence 36 months after SRP (98). Similar data have been described by Stephenson et al. (99).

In most contemporary series, organ-confined disease, negative SMs, and an absence of seminal vesicle and/or lymph node metastases were favorable prognostic indicators associated with a better disease-free survival of approximately 70-80%, in comparison with 40-60% in patients with locally advanced PCa (100).

Heidenreich et al. (101) reported on the oncological and functional outcome in 55 patients who underwent radical salvage therapy for locally recurrent PCa after various types of modern state-of-the-art RT, performed in or after the year 2000. Forty (72.7%) and 15 (27.3%) patients demonstrated organ-confined and locally advanced PCa, respectively. Eleven patients (20%) and seven patients (14%) had lymph node metastases and
positive surgical margins, respectively. In the multivariate analysis, significant predictors of organ-confined PCa with negative surgical margins were:

- Biopsy Gleason score prior to SRP ($P = 0.02$)
- < 50% positive biopsy cores ($P = 0.001$)
- PSADT > 12 months ($P = 0.001$)
- Low-dose brachytherapy ($P = 0.001$)

Urinary continence was achieved after a mean of 8 months in virtually all men after low-dose brachytherapy, while UI persisted in about 20% of patients who underwent EBRT or high-dose brachytherapy.

More recently, salvage laparoscopic radical prostatectomy (SLRP) has been suggested by Ahallal et al. The authors analysed the data for 15 patients who underwent SLRP for biochemical recurrences after RT. Continence recovered in about 50% of the patients, and erectile dysfunction occurred in nearly all of them. The biochemical control was similar to that with the open technique (104).

The current status of salvage robotic RP is still under investigation (105).

19.6.1.1 Summary of salvage radical prostatectomy

In general, SRP should be considered only for patients with low comorbidity, a life expectancy of at least 10 years, an organ-confined PCa < T2, Gleason score < 7, and preoperative PSA < 10 ng/mL. In all other patients, accurate preoperative staging is not easily defined after RT, increasing the risk not only for anterior and total extirpation procedures, but also for associated complications and reduced long-term disease-specific survival.

19.6.2 Salvage cryoablation of the prostate

In cases in which RT fails, salvage cryoablation of the prostate (SCAP) has been proposed as an alternative to SRP, as it has a potentially lower risk of morbidity and equal efficacy. However, the very few studies available have shown disappointing results. In a review of the use of SCAP for recurrent cancer after RT, the 5-year biochemical disease-free survival estimates ranged from 50% to 70%. With the use of third-generation technology, severe complications such as rectourethral fistulae have been significantly less common over the last decade than in the past (106).

According to Cespedes et al. (107), the risks of UI and erectile dysfunction at least 12 months after SCAP were as high as 28% and 90%, respectively. In addition, 8-40% of patients reported persistent rectal pain, and an additional 4% of the patients underwent surgical procedures for the management of treatment-associated complications.

With regard to the oncological outcome, studies have shown that a durable PSA response can be achieved in about 50% of patients with a pre-SCAP PSA < 10 ng/mL (108).

In a multicentre study reporting the current outcome of SCAP in 279 patients, the 5-year BCR-free survival estimate according to the Phoenix criteria was $54.5 \pm 4.9%$. Positive biopsies were observed in 15 of the 46 patients (32.6%) who underwent prostate biopsy after SCAP. The UI rate was 4.4%. The rectal fistulae rate was 1.2%, and 3.2% of patients had to undergo transurethral resection of the prostate (TURP) for removal of sloughed tissue (109).

A case-matched control study comparing SRP and SCAP was performed in men with recurrent PCa after RT. The authors compared the oncological outcomes of the two salvage treatment options after mean follow-up periods of 7.8 in the SRP group and 5.5 years in the SCAP group. The 5-year BCR-free survival was 61% following SRP, significantly better than the 21% detected after SCAP. The 5-year OS was also significantly higher in the SRP group (95% vs. 85%) (110).

19.6.3 Salvage brachytherapy for radiotherapy failure

Experience with salvage brachytherapy for patients in whom RT has failed is very limited. In a small study including 11 patients treated with high-dose brachytherapy after RT failure, Jo et al. reported that seven of the 11 patients were free of recurrent disease after a mean of 29 months of follow-up (111). Beyer (112) reported that 34-53% of patients remained free of biochemical relapse after 5 years, with local cancer control achieved in 98% of the patients. However, the complication rate was quite high:

- 27% of the patients became incontinent.
- 14% needed palliative TURP due to acute urinary retention.
• 4% developed rectal ulcers.
• 2% required a permanent colostomy.

A recent review of salvage brachytherapy for RT failure by Gomez-Veiga et al. reported 5-year BCR-free survival rates ranging from 20% to 87%. A single study reported a 10-year BCR-free survival rate of 54% (113).

Moman et al. (114) retrospectively evaluated the outcome and toxicity after salvage iodine-125 implantation in 31 patients with locally recurrent PCa after primary iodine-125 implantation and EBRT. The mean follow-up period was 9 years (SD ± 4). The rates of freedom from BCR were 51% and 20% after 1 and 5 years of follow-up, respectively. Grade 1, 2, or 3 toxicity of the genitourinary tract was reported in 29%, 58%, and 3% of the patients, respectively, in the acute phase, and in 16%, 39%, and 19%, respectively, in the late phase. Grade 1, 2, or 3 toxicity of the gastrointestinal tract was reported in 45%, 10%, and 0% of the patients, respectively, in the acute phase, and in 48%, 3%, and 6%, respectively, in the late phase.

In conclusion, freedom from BCR after salvage iodine-125 implantation for locally recurrent PCa following RT is limited, and both genitourinary and gastrointestinal toxicity occur frequently.

19.6.4 Observation
Patients who have signs of only local recurrence (i.e., low-risk patients with late recurrence and a slow PSA rise) who do not wish to undergo second-line curative options are best managed by observation alone. A retrospective cohort analysis of HT vs. watchful waiting in 248 men with PSA failure after RT showed no advantage for HT in the subgroup of men with a PSADT of > 12 months after RT. The 5-year metastasis-free survival rate was 88% with hormone therapy versus 92% with watchful waiting (P = 0.74) (115).

19.6.5 High-intensity focused ultrasound
Experience with high-intensity focused ultrasound (HIFU) for the treatment of locally recurrent PCa after RT is limited to a few retrospective studies. Zacharakis et al. (116) investigated the oncological and functional outcome of HIFU in a cohort of 31 men with biopsy-proven locally recurrent PCa following EBRT. The mean preoperative PSA level was 7.73 ng/mL (range 0.20-20.0 ng/mL). The patients were followed up for a mean of 7.4 months (range 3-24 months). Side effects included stricture or intervention for necrotic tissue in 11 patients (35%), urinary tract infection or dysuria syndrome in eight (26%), and UI in two (6%). Rectourethral fistulae occurred in two men (7%). Overall, 71% had no evidence of disease following salvage HIFU.

Murat et al. (117) evaluated the safety and efficacy of salvage HIFU in 167 patients with local PCA recurrence after EBRT and assessed prognostic factors for optimal patient selection. Local cancer control was achieved with negative biopsy results in 122 patients (73%). The median PSA nadir was 0.19 ng/mL. The mean follow-up period was 18.1 months (range 3-121 months). Seventy-four patients did not require HT. The actuarial 5-year OS rate was 84%. The actuarial 3-year progression-free survival was significantly lower in case of:
  • High pre-EBRT stage (with estimates as low as 53%, 42%, and 25% for low-risk, intermediate-risk, and high-risk patients, respectively).
  • High pre-HIFU PSA.
  • Use of ADT during PCa management.

Specifically, patients in the intermediate-risk and high-risk groups had a 1.32-fold and 1.96-fold higher risk, respectively, of any-cause mortality in comparison with the low-risk group. Moreover, patients treated with ADT had also a 2.8-fold higher risk of death in comparison with those who did not undergo ADT. No rectal complications were observed. Urinary incontinence accounted for 49.5% of the urinary sphincter implantations required in 11% of patients.

Urinary incontinence and the development of rectourethral fistulae are the most significant complications of salvage HiFU therapy (116-118). About 30% of men develop some form of incontinence, with significant UI treated with an artificial urinary sphincter in about 10% of patients. The oncological control rate after a short median follow-up period of about 2 years is 30-40%.
19.6.6 Guidelines for the management of PSA relapse after radiotherapy

20. CASTRATION-RESISTANT PCA (CRPC)

20.1 Background
Cancer of the prostate is a heterogeneous disease. Our knowledge of the mechanisms involved in androgen-independent prostate cancer, which is now known as castration-resistant prostate cancer (CRPC), remains incomplete, but is starting to become clearer (1,2). An alteration in normal androgen signalling is thought to be central to the pathogenesis of CRPC (3). It is mediated through two main, overlapping, mechanisms, which are androgen-receptor (AR)-independent and AR-dependent.

20.1.1 Androgen-receptor-independent mechanisms
Androgen-receptor-independent mechanisms may be associated with the deregulation of apoptosis through the deregulation of oncogenes. High levels of bcl-2 expression are seen with greater frequency as PCa progresses. The regulation of microtubule integrity may be a mechanism through which bcl-2 induces its anti-apoptotic effect (4,5). Indeed, most drugs that are active in CRPC work by inhibiting microtubule formation. The tumour suppressor gene p53 is more frequently mutated in CRPC. Overexpression of bcl-2 and p53 in prostatectomy specimens has been shown to predict an aggressive clinical course (6,7). Clinical trials are underway to target the bcl-2 pathway (8), and the MDM2 (mouse double minute 2) oncogene (9) and the PTEN
(phosphatase and tensin homolog) suppressor gene may also be involved (10).

20.1.2 Androgen-receptor-dependent mechanisms

Direct AR-dependent mechanisms comprise the main pathway. Ligand-independent androgen receptor (AR) activation has been suspected, such as the tyrosine-kinase-activated pathway [insulin-like growth factor-1, keratinocyte growth factor, and epidermal growth factor (EGF)]. EGF is a potent mitogen of prostate stromal and epithelial cells. It is produced in high levels locally and acts as a paracrine stimulator. In AR-independent tumours, autocrine stimulation may become more important, which could allow unregulated growth.

Androgen receptor amplification and overexpression are observed in one-third of CRPC tissues (11,12) and may lead to AR hypersensitivity. Androgen receptor mutations may lead to a functional change in receptor function (13). At the same time, there is an intracellular increase in androgens from in-situ conversion (14,15). This increase may be secondary to an increase in the enzymes involved in intracellular androgen synthesis (16).

Androgen receptor mutations are found in only a subpopulation of tumour cells, therefore, they are unlikely to be responsible for the entire spectrum of the AR-independent state (17). The AR mutations might be related to the selective pressure of anti-androgens (17). The recent discovery of gene fusion between the androgen-driven TMPRSS2 and the EGR-ETS oncogene family (18) raises the question of oncogene regulation through androgen regulation pathways. In gene fusion, an androgen-responsive element from an androgen-regulated gene becomes associated with genes that are usually not androgen-regulated, so that they too become subject to androgen regulation. Currently, their implication in CRPC is hypothetical. Even in castrated patients, metastatic tissues have repeatedly shown high levels of androgens, suggesting a high level of intracrine synthesis (16,19). It is possible that a high intraprostatic cholesterol level can activate specific androgen pathways (20).

20.2 Definition of relapsing prostate cancer after castration

The precise definition of recurrent or relapsed PCa remains controversial and several groups have published practical recommendations for defining CRPC (19,20).

Various different terms have been used to describe PCa that relapses after initial hormonal ablation therapy, including hormone-refractory PCa, androgen-independent cancer and hormone-independent cancers. In recent years, the term CRPC has become more frequently used than hormone refractory or androgen-independent PCa. This is based predominantly on recent findings suggesting that advancing PCa is not uniformly refractory to further hormonal manipulation and that androgens and disease progression are frequently dependent on androgen receptor interactions. Castration-resistant prostate cancer, which is still hormone sensitive, has been clearly characterised, with new drugs targeting the AR, such as MDV3100 (Enzalutamide), or androgen synthesis, via CYP 17 inhibition, such as abiraterone acetate or TAK700 (21). Table 21 lists the key defining factors of CRPC.

Table 21: Definition of CRPC

| Castrate serum levels of testosterone < 50 ng/dL or < 1.7 nmol/L. |
| Three consecutive rises of PSA, 1 week apart, resulting in two 50% increases over the nadir, with PSA > 2 ng/mL. |
| Anti-androgen withdrawal for at least 4 weeks for flutamide and for at least 6 weeks for bicalutamide* |
| PSA progression, despite consecutive standard hormonal manipulations† |

* Either anti-androgen withdrawal or one secondary hormonal manipulation should have been done to fulfill the criteria for CRPC if patients have been treated with anti-androgens in the context of maximum androgen blockade or step-up therapy following PSA progression after failure of LHRH treatment.

† Progression or appearance of two or more bone lesions on bone scan or soft tissue lesions using RECIST (Response Evaluation Criteria in Solid Tumours) with nodes ≥ 2 cm in diameter.

20.3 Assessing treatment outcome in CRPC

In general, the therapeutic outcome should be assessed using the guidelines for the evaluation of treatment response in solid tumours, recently published by the RECIST group (Response Evaluation Criteria In Solid Tumours) (22). However, 80-90% of patients do not have bi-dimensionally measurable disease. Patients with primarily soft tissue cancers often have a different prognosis to those with only bone metastases. Osteoblastic bone metastases remain difficult to quantify accurately. Magnetic resonance imaging (MRI) might be useful for assessing axial metastases (23). The cause of death in PCa patients is often unreliable, therefore a more valid end-point might be OS rather than a disease-specific one (24).
20.3.1 **PSA level as marker of response**

Many contemporary studies use PSA as a marker of response, even though there is no consensus about the magnitude and duration of a decline in PSA level. Although PSA is used as a rapid screening tool to test the activity of new agents, there is conflicting evidence about the role of PSA as a response marker. Trials of the vaccines sipuleucel-T (Provenge) (25) and TRICOM (PROSTVAC) (26) have demonstrated a significant OS benefit without any PSA change, raising questions about the value of PSA response for non-hormonal non-cytotoxic drugs (27).

In addition, wide fluctuations have been seen in PSA values due to a transient effect of drugs on PSA production. The effect of drugs on PSA expression should be considered when interpreting PSA response data, which should be viewed together with other clinical data (28-35).

Nevertheless, it has been shown reproducibly that ≥ 50% PSA decline in pre-treatment PSA following therapy carries a significant survival advantage (36,37).

An improved PSA response was also associated with prolonged survival in the TAX 327 study, with a median survival of 33 months when the PSA was normalised (< 4 ng/mL) vs. 15.8 months for an abnormal PSA. This study also showed that a PSA response was not a surrogate marker for survival. Even though the same PSA response rate was found in both docetaxel arms (45%), improved survival only occurred with the 3-weekly docetaxel regimen. According to the most recent evaluation of the TAX 327 and SWOG 99-16 studies, a PSA detection of ≥ 30% is associated with a significant survival benefit (38,39).

20.3.2 **Other parameters**

Evaluation of molecular markers is just beginning. The most frequently described and probably most interesting tool is the circulating tumour cell (CTC) count, which has been developed in parallel with abiraterone. The CTC count was related to survival in several trials (40-42) and might become a surrogate marker for survival. The Food and Drug Administration (FDA) has recently approved an assay for CTCs. In patients with symptomatic bone lesions, pain reduction or complete pain relief may be used as parameters to assess palliative therapeutic response (43). In a landmark analysis of TAX 327, PSA response and pain response, but not QoL response, were independently associated with survival (44).

20.3.3 **Recommendations for assessing therapeutic response**

In everyday practice, the evaluation of treatment response must be based on symptom improvement, prolonged survival, or other pre-defined targets. The Prostate Cancer Working Group 2 (PCWG2) recommends that investigators measure early outcomes by the changes in the individual disease manifestations present initially for both cytotoxic and non-cytotoxic drugs with the same methods used at enrolment (19). If a protocol defines a composite end-point for progression, the specified progression in any measure (with the exception of early changes in PSA or pain) overrides a change or improvement in other measures.

</tbody>
</table>

CRPC = castration-resistant prostate cancer; HRQoL = health-related quality of life; PSA = prostate-specific antigen; RECIST = response evaluation criteria in solid tumours.
20.4 Androgen deprivation in castration-resistant PCa
The existence of androgen-resistant PCa shows that disease progression occurs despite castration. The castration levels of testosterone must therefore be documented and a serum testosterone level < 50 ng/dL (1.7 nmol/L) should be documented at initial relapse on hormonal therapy (45). Continued testicular androgen suppression in CRPC has a minimal overall effect. The recommendation to continue ADT with LHRH analogues, despite PSA progression, is based on the data of Manni et al. (46). They demonstrated significantly lower survival rates in patients without complete androgen blockade (CAB). However, these data have been challenged by two trials that showed only a marginal survival benefit for patients remaining on LHRH analogues during second- and third-line therapies (47,48). However, in the absence of prospective data, the modest potential benefits of a continuing castration outweigh the minimal risk of treatment. Androgen suppression should therefore be continued indefinitely in these patients.

20.5 Secondary hormonal therapy
For the patient with progressive disease after ADT, there are many therapeutic options. They include anti-androgen withdrawal, addition of anti-androgens, anti-androgen replacement, oestrogenic compounds, adrenolytic agents, and novel approaches (49). Figure 1 summarises the treatment modalities and expected responses.

Figure 1: Flowsheet of the potential therapeutic options after PSA progression following initial hormonal therapy

LHRH = luteinising hormone releasing hormone; Abiraterone A: abiraterone acetate
* Median cannot be compared because patients included in trials did not have the same characteristics

20.6 Anti-androgen withdrawal syndrome
Anti-androgen withdrawal syndrome is a critical discovery in understanding the biology of androgen independence, interpreting clinical trials, and treating patients (50-53). Approximately one-third of patients respond to anti-androgen withdrawal, as indicated by a ≥ 50% PSA decrease, for a median duration of approximately 4 months. Anti-androgen withdrawal responses have also been reported with bicalutamide and megestrol acetate (54-59). Recently, in the SWOG 9426 trial, PSA progression despite CAB was reported in a subgroup of 210 patients with an M0 or M1 stage tumour (60). A response was observed in 21% of patients, even though there was no radiographic response. Median PFS was 3 months, with 19% (all M0) having PFS ≥ 12 months*. Increased PFS and OS were associated with longer use of non-steroidal drugs, lower PSA at baseline and M0-stage. These results were obtained with patients on CAB.
following androgen withdrawal. No data were available on the withdrawal effect following second-line anti-
androgen treatment.

In conclusion, androgen withdrawal must be systematically considered as a first-line modality in relapsing patients, even if its efficacy is limited (LE: 2).

20.7  Classical hormonal treatment alternatives after CRPC occurrence
Simple old fashioned modalities have been reported, without any associated survival benefit ever reported.

20.7.1  Bicalutamide
Bicalutamide has a dose response, with higher doses producing a greater reduction in PSA level (61). The largest cohort so far is based on 52 CRPC patients treated with 150 mg bicalutamide (62). A palliative effect was clear and a 20% PSA response (at least 50% decrease) was observed, without any link to the palliative effect. Based on the affinity of dihydrotestosterone for the AR, a large randomised trial (TARP) is ongoing comparing the effectiveness of 50 mg bicalutamide combined with either dutasteride or placebo in non-metastatic CRPC (63). The addition of a non-steroidal anti-androgen to gonadal suppression at the time of PSA failure appears to result in declining PSA in only a few patients (64,65).

20.7.2  Switching to an alternative anti-androgen therapy
There has been recent interest in another simple modality, namely, the alternative anti-androgen therapy (66). After CAB was stopped in 232 patients with progressive disease (76% with stage M1b), a withdrawal effect was observed in 31 men (15.1%). Second-line hormonal treatment was performed by giving an alternative non-steroidal drug (i.e. initial flutamide was replaced by bicalutamide and vice versa). An overall > 50% decline in PSA was observed in 83 men (35.8%), irrespective of any previous withdrawal effect, which lasted > 6 months. The higher the PSA at the start of second-line therapy, the shorter was the FPS and the lower was the PSA response rate.

20.7.3  Anti-androgen withdrawal accompanied by simultaneous ketoconazole
The adrenal glands secrete approximately 10% of circulating androgen in humans. This can be inhibited using aminoglutethimide, ketoconazole and corticosteroids (67-71) resulting in a PSA response in ~ 25% of patients of ~ 4 months duration. The simultaneous addition of ketoconazole to anti-androgen withdrawal, produced a significantly increased PSA response (32% vs. 11%) and a longer time to PSA progression (8.6 vs. 5.9 months) compared to anti-androgen withdrawal alone (71).

20.7.4  Oestrogens
Prostate cancer usually expresses oestrogen receptors, which are upregulated after androgen ablation in animal models. Diethylstilboestrol (DES) (72-74) achieved a positive PSA response in 24% and 80% of patients, with an overall estimated survival of 83% at 2 years. However, even at low doses of DES, about one-third (31%) of patients developed deep venous thrombosis and 7% experienced myocardial infarction.

20.8  Novel hormonal drugs targeting the endocrine pathways
In the past 2 years, following early phase II/III trials in patients with CRPC, new compounds appeared for treating CRPC (Section 19.4). Most have been developed post docetaxel, but abiraterone acetate and MDV 3100 have been used before chemotherapy. The initial results have been recently published from the large phase III trial COU-AA-302, in which 1088 chemonaive CRPC patients were randomised to abiraterone acetate and placebo, both combined with prednisone (75). Patients were diagnosed with CRPC according to the PCWG2 criteria, and were Eastern Cooperative Oncology Group (ECOG) performance status 0 or 1 and asymptomatic or mildly symptomatic. The study had two joint primary end-points: OS and radiographic PFS. The results reported are from the second preplanned interim analysis. After a median follow-up of 22 months, there was significant radiological PFS (median 16.5 vs. 8.3 months, HR: 0.53, P < 0.01 below the prespecified boundary). Regarding OS, there was a trend (median not reached vs. 27.2 months, HR: 0.75, P = 0.01). However, this value was above the prespecified P value for the second interim analysis (P < 0.001), leading to a non-significant difference. All the subgroup analyses and secondary end-points consistently favoured the abiraterone arm. Side effects related to mineralocorticoids and liver function were more frequent with abiraterone, but mostly grade 1/2. These positive results have led to European Medicines Agency (EMEA) drug approval but it must be emphasised that one of the primary end-points has not yet been reached, leading to an overall inconclusive result.

Regarding MDV3100, accrual for the phase III trial (PREVAIL) is complete but no results are available to date.

20.9  Non-hormonal therapy
Several chemotherapeutic options have been reported from phase III trials in CRPC (Table 22). Several trials
are underway, using different approaches through all the known pathways. A detailed review is far beyond the scope of these guidelines (1). Docetaxel is currently the standard of care.

20.9.1 Docetaxel regimen
A significant improvement in median survival of 2-2.5 months occurred with docetaxel-based chemotherapy compared to mitoxantrone + prednisone therapy (76,77). In the SWOG 99-16 trial, pain relief was similar in both groups, although side effects occurred significantly more often with docetaxel than with mitoxantrone.

The standard for first-line cytotoxic chemotherapy is docetaxel using the same regimen as in the TAX 327 trial, that is, 75 mg/m² 3 weekly combined with prednisone 5 mg BID, up to 10 cycles of survival, and palliation is the main target. The weekly regimen is not associated with improved survival and does not appear to be better tolerated.

The patients considered for docetaxel represent a heterogeneous population. Several poor prognostic factors have been described, such as a PSA level > 114 ng/mL, PSA doubling time (PSA-DT) < 55 days, or the presence of visceral metastases (78). A better risk group definition has been recently presented, based on the TAX 327 study cohort. The predictive factors were visceral metastases, pain, anaemia (Hb < 13 g/dL), bone scan progression, and prior estramustine before docetaxel. Patients were categorised into three risk groups: low risk (0 or 1 factor), intermediate (2 factors) and high risk (3 or 4 factors), leading to three different lengths of median OS: 25.7, 18.7 and 12.8 months, respectively (39). In addition, two independent studies have suggested that improved survival can be predicted by C-reactive protein (CRP) levels < 8 mg/L (HR, 2.96) (79,80). Age by itself is not a contraindication to docetaxel (81).

EMP = estramustine; HC = hydrocortisone; 1p < 0.000 compared to mitoxantrone; 2p = 0.001 compared to mitoxantrone.

20.9.2 Other classical regimen
20.9.2.1 Mitoxantrone combined with corticosteroids
Mitoxantrone combined with corticosteroids (82,83) has been extensively studied; primarily in patients with symptomatic bone lesions due to CRPC. Palliation is effective with a clear PSA response and increased PFS, leading to a significant improvement in QoL, no survival benefit was ever observed.

20.9.2.2 Other chemotherapy regimen
The synergy observed for estramustine combined with other drugs that target microtubule action has generated promising results in prospective clinical trials. Combination with vinblastine is the most frequently studied
combination. Significant PSA and measurable responses have been reported, without any survival benefit (84). A recent meta-analysis (85) concluded that addition of estramustine to chemotherapy increased the time to PSA progression and OS. However, there was a significant increased risk (up to 7%) of thromboembolic events, (86), requiring systematic prevention with coumadin. Intravenous cyclophosphamide, or new oral formulations have been tested, without any clear survival benefit (87,88). Cisplatin and carboplatin have activity as single agents against PCa and have a synergistic effect, as with estramustine. Combination of estramustine, etoposide and cisplatin (or carboplatin) has significant activity against poorly differentiated CRPC. Combination of estramustine, etoposide and paclitaxel has high response rates (89,90). Preliminary results from phase II with alternative chemotherapy regimens have been reported (89,91-93), including pegylated doxorubicin, vinorelbine; a combination of paclitaxel, carboplatin and estramustine; combination of vinblastine, doxorubicin and radionuclides; and combination of docetaxel and mitoxantrone. The lack of large phase III trials and unknown long-term efficacy are major problems associated with all these studies. Therefore none of the above drugs are considered as clear valid options in CRPC.

20.9.3 Specific bone-targeted therapies
Bone is a primary target for prostatic metastatic cells, which forms a rationale for bone-protective drugs that prevent cancer cells from colonising and developing in bone. Besides zoledronic acid and denosumab (see Section 12.7.1), other drugs, that specifically target the endothelin-1 axis have been tested. The first of these (atarsentan) resulted in clear biological responses, but questionable clinical results (94), possibly secondary to an inappropriate trial design. Second-generation blockers (zibotentan) have been tried in large phase III trials in metastatic and non-metastatic CRPC but finally stopped due to negative results in relation to OS (95).

The only bone-specific drug that is associated with a survival benefit is alpharadin, a radium 223 α-emitter. In the large phase III trial (ALSYMPCA) 921 patients with symptomatic CRPC, who failed or were unfit for docetaxel therapy, were randomised to six injections of 50 kBq/kg alpharadin or placebo. The primary endpoint was OS. The results of this trial have been repeatedly presented but only partially published (96,97). Alpharadin significantly improved OS by 3.6 months. The associated toxicity was minimal, specially the hematologic one, and did not differ significantly from that in the placebo arm.

20.9.4 Vaccine
In 2010, a phase III trial of Sipuleucel T showed a survival benefit in 512 CRPC patients (97). This was the first time that a PCA vaccine had shown a benefit and led to FDA approval and a submission to the EMEA. Sipuleucel T is an active cellular immunotherapy agent consisting of autologous peripheral blood mononuclear cells, activated in vitro by a recombinant fusion protein comprising prostatic acid phosphatase fused to granulocyte–macrophage colony-stimulating factor, which is an immune-cell activator. In the above trial, patients with metastatic CRPC, with PSA > 5 ng/mL, castrate testosterone level, and no visceral metastases, were randomised to three infusions 2 weeks apart with Sipuleucel T or placebo. Up to two previous chemotherapy regimens were allowed (effective in 19.6% Sipuleucel T treated patients and in 15.2% respectively). The main objective was OS. After a median follow-up of 34 months, the median survival was 25.8 months in the Sipuleucel T group compared to 21.7 months in the placebo group, leading to a significant point was OS. The results of this trial have been repeatedly presented but only partially published (96,97). Alpharadin significantly improved OS by 3.6 months. The associated toxicity was minimal, specially the hematologic one, and did not differ significantly from that in the placebo arm.

The COU-AA-302 trial raises the question of prechemotherapy use of this new compound, and the possible selection criteria between second-line chemotherapy or hormonotherapy. Also some very preliminary retrospective observations might be helpful, it is so far impossible to predict which subset of patients is most likely to respond to one specific second-line treatment modality. Finally, the only indication for chemotherapy in CRPC non-metastatic patients is inside clinical trials and patients should be advised to participate.
20.11 Salvage treatment after first-line docetaxel

All patients who receive docetaxel-based chemotherapy for CRPC will progress, thus, there have been many clinical trials investigating the role of salvage chemotherapy. Recently, there have been major improvements in this situation. Two treatment possibilities are now available: new hormonal treatment or new chemotherapy regimens. The results suggest that the most appropriate approaches are cabazitaxel, intermittent docetaxel chemotherapy, and potentially, molecular-targeted therapy.

Several groups have used second-line intermittent docetaxel in patients who had clearly responded to first-line docetaxel. In general, a PSA response can be achieved in about 60% of patients with a median time to progression of about 6 months, while treatment-associated toxicity is minimal and similar to that of first-line docetaxel. Another, recently identified approach is molecular-targeted therapy although more research is needed in larger groups of patients.

Platinum-based chemotherapeutic regimens have been investigated in patients with CRPC. Although more research is needed in larger groups of patients. First-line docetaxel chemotherapy (101), intermittent docetaxel chemotherapy (102), and potentially, molecular-targeted therapy (103, 104) have been tested in phase II/III trials without any positive impact on the primary end-point. The G-Vax trial was stopped prematurely because of a significantly higher mortality in the treatment arm as compared to the docetaxel control arm.

20.11.1 Cabazitaxel

Cabazitaxel is a taxane derivative with some significant differences compared to docetaxel. Positive results have been published from a large prospective, randomised, phase III trial (TROPIC trial) comparing cabazitaxel + prednisone vs. mitoxantrone + prednisone in 755 patients with CRPC, who had progressed after or during docetaxel-based chemotherapy (100). Patients received a maximum of 10 cycles of cabazitaxel (25 mg/m²) or mitoxantrone (12 mg/m²) plus prednisone (10 mg/day), respectively. Overall survival was the primary end-point, and PFS, treatment response and safety were secondary end-points. An OS benefit (15.1 vs. 12.7 months, P < 0.0001) was observed in the cabazitaxel arm. There was also a significant improvement in PFS (2.8 vs. 1.4 months, P < 0.0001), objective response rate according to RECIST criteria (14.4% vs. 4.4%, P < 0.005), and PSA response rate (39.2% vs. 17.8%, P < 0.0002). Treatment-associated WHO grade 3/4 side effects developed significantly more often in the cabazitaxel arm, particularly haematological (68.2% vs. 47.3%, P < 0.0002) and non-haematological (57.4% vs. 39.8%, P < 0.0002) toxicity (100). This drug should be administered by physicians with expertise in handling neutropenia and sepsis, possibly with granulocyte colony-stimulating factor.

20.11.2 Enzalutamide (MDV3100)

Enzalutamide (formerly known as MDV3100) is a novel anti-androgen that blocks AR transfer to the nucleus, in contrast to currently available drugs with which AR is able to transfer to the nucleus. Enzalutamide is used as a once-daily oral treatment. The planned preliminary analysis of the AFFIRM study was published in 2012 (109). This trial randomised 1,199 patients with metastatic CRPC in a 2/1 fashion between enzalutamide or placebo. The patients had progressed after docetaxel treatment, according to the PCWG2 criteria. Corticosteroids were not requested but possible, and therefore received by 30% of the population. The primary end-point was OS, with an expected HR benefit of 0.76 in favour of enzalutamide. After a median follow-up of 14.4 months, the median survival in the enzalutamide group was 18.4 months compared to 13.6 months in the placebo arm (HR: 0.63, P < 0.001). This led to the recommendation that the study be halted and unblinded. The benefit was observed irrespective of age, baseline pain intensity, and type of progression. All the secondary objectives were in favour of enzalutamide (PSA, soft tissue response, QoL, time to PSA or objective progression). No difference in terms of side effects were observed in the 2 groups, with a lower incidence of grade 3-4 side effects in the enzalutamide arm. There was a 0.6% incidence of seizures in the enzalutamide group compared to none in the placebo arm.

20.11.3 Abiraterone acetate

Abiraterone acetate is a CYP17 inhibitor. It is used once daily combined with prednisone twice daily (10 mg/day). Positive preliminary results of the large phase III COU-AA-301 trial were reported after a median follow-up of 12.8 months (110) and the final results have been reported more recently (111). A total of 1,195 patients with metastatic CRPC were randomised in a 1/1 fashion between abiraterone acetate or placebo. All patients had progressive disease based on the PCWG2 criteria after docetaxel therapy (with a maximum of two previous chemotherapeutic regimens). The primary end-point was OS, with a planned HR of 0.8 in favour of abiraterone. After a median follow-up of 20.2 months, the median survival in the abiraterone group was 15.8 months compared to 11.2 months in the placebo arm (HR: 0.74, P < 0.001). The benefit was observed irrespective of age, baseline pain intensity, and type of progression. All the secondary objectives were in favour of abiraterone.
(PSA, radiologic tissue response, time to PSA or objective progression). With regard to previous docetaxel therapy, no benefit was observed in the abiraterone arm when docetaxel had been used for < 3 months, but the benefit remained independent of the delay since the last dose of docetaxel (less or more than 3 months). The incidence of the most common grade 3/4 side effects did not differ significantly between both arms, but mineralocorticoid-related side effects were more frequent in the abiraterone group, mainly grade 1/2 (fluid retention, oedema or hypokalaemia). The longer follow-up did not lead to an unexpected increased in toxicity compared to the preliminary analysis.

However, the choice between third-line hormonal treatment (using enzalutamide or abiraterone) or second-line chemotherapy (cabazitaxel) remains unclear with no clear decision-making findings published. They are urgently awaited because nothing is known regarding the optimal sequencing of drugs. The cost of each drug will be a major challenge to public health.

CRPC = castration-resistant prostate cancer.

20.12 Palliative therapeutic options: bone targeted therapies in CRPC
CRPC is usually a debilitating disease, often affecting the elderly male. A multidisciplinary approach is often required with input from medical oncologists, radiation oncologists, urologists, nurses, psychologists and social workers (112).

20.12.1 Painful bone metastases
Most patients with CRPC have painful bone metastases. External beam radiotherapy is highly effective (113), even as single fraction (114). The two radioisotopes, strontium-89 and samarium-153, can partially or completely decrease bone pain in up to 70% of patients, but should not be given too late when pain is intractable. Early use can give rise to myelosuppression, making subsequent chemotherapy more difficult (115), even though a recent phase I trial has demonstrated manageable haematological toxicity with repeated administration of docetaxel and samarium-153. The use of samarium-153 as consolidation therapy, following a clear docetaxel response, may also help with initially painful bone metastases (116). Apart from the OS benefit, the α-radioisotope emitter, radium-223, has also shown a significant palliative effect in patients with painful bone metastases (117). The full results of this study are urgently awaited.

20.12.2 Common complications due to bone metastases
Common complications due to bone metastases include bone pain, vertebral collapse or deformity, pathological fractures and spinal cord compression. Osteoporosis may also cause fractures and should be prevented (see above). Cementation is an effective treatment for painful fracture, clearly improving both pain and QoL (118). However, it is still important to offer standard palliative surgery, which can be effective for managing osteoblastic metastases (119,120). Impending spinal cord compression is an emergency. It must be recognised early and patients should be educated to recognise the warning signs. Once suspected, high-dose corticosteroids must be given and MRI performed as soon as possible. A systematic neurosurgery consultation should be planned to discuss a possible decompression (121). Otherwise, external beam radiotherapy, with or without systemic therapy, is the treatment of choice.

20.12.3 Bisphosphonates
Bisphosphonates have been used to inhibit osteoclast-mediated bone resorption and osteoclast precursors in CRPC. In the largest single phase III trial to date (122), 643 patients who had CRPC with bone metastases were randomised to receive zoledronic acid, 4 or 8 mg every 3 weeks for 15 consecutive months, or placebo. At 15 and 24 months of follow-up, patients treated with 4 mg zoledronic acid had fewer skeletal-related events (SREs) compared to the placebo group (44% vs. 33%, P = 0.021) and fewer pathological fractures (13.1% vs. 22.1%, P = 0.015). Furthermore, the time to first SRE was longer in the zoledronic acid group, thus improving QoL. Patients were initially randomised to 4 or 8 mg of zoledronic acid, but the 8 mg dosage was later modified to 4 mg because of toxicity. No survival benefit was seen in any trial with bisphosphonates, except in a post hoc analysis of an old compound without any significant impact on SREs (123).
Currently, bisphosphonates can be offered to patients with CRPC bone metastases to prevent skeletal complications, even if the best dosing interval is unclear. At present, it is every 3 weeks or less. The toxicity (e.g., jaw necrosis) of these drugs, especially aminobisphosphonate, must always be kept in mind (122). Patients should have a dental examination before starting bisphosphonate therapy. The risk of jaw necrosis is increased by a history of trauma, dental surgery or dental infection, as well as intravenous long-term bisphosphonate administration (124).

Pain due to bone metastases is one of the most debilitating complications of CRPC. Bisphosphonates have proven to be highly effective in reducing bone pain, but so far this has been investigated only in small, open trials. Data from these trials suggest that bisphosphonates have a low side-effect profile (125-127).

Bisphosphonates should be considered early in the management of symptomatic CRPC. Critical issues of palliation must be addressed when considering additional systemic treatment, including management of pain, constipation, anorexia, nausea, fatigue and depression, which often occur (i.e., palliative external beam radiation, cortisone, analgesics and antiemetics).

20.12.4 **RANK ligand inhibitors**

Denosumab is a fully human monoclonal antibody directed against RANKL (receptor activator of nuclear factor κB ligand), a key mediator of osteoclast formation, function, and survival. In M0 CRPC, denosumab has been associated with increased bone-metastasis-free survival compared to placebo (median benefit: 4.2 months, HR: 0.85; P = 0.028) (128). However, this benefit did not translate into a survival difference (43.9 compared to 44.8 months, respectively). The practical impact of this finding remains under discussion. The efficacy and safety of denosumab (n = 950) compared with zoledronic acid (n = 951) in patients with metastatic CRPC was assessed in a phase III trial. Denosumab was superior to zoledronic acid in delaying or preventing SREs, as shown by time to first on-study SRE (pathological fracture, radiation or surgery to bone, or spinal cord compression) of 20.7 vs. 17.1 months, respectively (HR 0.82; P = 0.008). Denosumab also extended time to first and subsequent on-study SRE (HR 0.82; P = 0.008). Both urinary NTX and BAP were significantly suppressed in the denosumab arm compared with the zoledronic acid arm (P < 0.0001 for both). However, these positive findings were not associated with any survival benefit. Denosumab is FDA approved for preventing SREs in patients with bone metastases from solid tumours, and EMEA approval is pending.

</tbody>
</table>
If chemotherapy is considered in patients with symptomatic bone metastases due to CRPC, either docetaxel or mitoxantrone with prednisone or hydrocortisone are viable options. If not contraindicated, docetaxel is the preferred agent based on the significant advantage in pain relief.

In patients with relapse following first-line docetaxel chemotherapy cabazitaxel, abiraterone and enzalutamide are regarded as first-choice options for second-line treatment.

Second-line docetaxel can be offered to previously responding docetaxel-treated patients. Otherwise, treatment should be tailored to the individual patient. In case patients are not eligible for cabazitaxel, abiraterone or enzalutamide, docetaxel re-challenge is an option.

In men with CRPC with symptomatic bone metastases, who are ineligible for or progressing after docetaxel treatment with 223Ra (alpharadin) has shown a survival benefit.

CRPC = castration-resistant prostate cancer; PSA = prostate-specific antigen.

Conflict of interest
All members of the Prostate Cancer Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

8.1 Introduction 52
8.2 Which investigations for which patients, and when? 52
1. METHODOLOGY

1.1 Introduction
The European Association of Urology (EAU) Renal Cell Cancer (RCC) Guidelines Panel has compiled these clinical guidelines to provide urologists with evidence-based information and recommendations for the management of renal cell cancer. The RCC panel is an international group consisting of 10 clinicians with particular expertise in this field of urological care.

The guideline update methodology is detailed below, but for a substantial portion of the text the evidence base has been upgraded. The aim is to progress this further in the years to come.

Without the inspiration and practical assistance provided by Prof. James N’Dow, this would have been unattainable. We owe him and his UCAN team (Urological Cancer Charity, Scotland) a debt of gratitude. In the course of 2012, Dr. Thomas Lam joined our efforts and his support of the review team at his home institution (Aberdeen University Hospital), and in particular of the three young urologists who joined the RCC panel last year (Dr. Saeed Dabestani, Dr. Fabian Hofmann and Dr. Lorenzo Marconi), has been invaluable. Drs. Dabestani, Hofmann and Marconi have taken on the data management of the systematic reviews underpinning this 2013 publication.

For this 2013 update, the Panel did not manage to complete all systematic reviews in a timely fashion. As a result, sections of the document have been updated following a structured literature assessment. The focus for 2014 is to proceed with the systematic review, aiming for the complete guidelines document to be based on a uniformly high level of data work-up.

1.2 Methodology
1.2.1 Data identification
All chapters of the 2013 RCC Guidelines publication have been updated. As mentioned above, the consistency of the data work-up will differ between sections. An overview is presented in Table 1.

Table 1: Description of update and summary of review methodology

<td>The chapter has been updated using a traditional narrative review</td>
</tr>
</tbody>
</table>

For the parts of the guideline that have been updated by way of a systematic review, the review methodology is outlined in detail elsewhere (1). In brief, a systematic review of the literature was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (2). Important topics and questions were prioritised by the panel for the present update. Elements for inclusion and exclusion, including patient population, intervention, comparison, outcomes, study design, and search terms and restrictions were developed using an iterative process involving all members of the panel, to achieve consensus. Individual literature searches were conducted separately for each update question, and in most instances the search was conducted up to the end of September 2012. Two independent reviewers screened abstracts and full texts, carried out data abstraction and assessed risk of bias. The results were presented in
tables showing baseline characteristics and summaries of findings. A narrative synthesis of the evidence was produced.

The remaining parts of the guideline have been updated using a traditional narrative review strategy. Structured literature searches using an expert consultant were designed. Searches were carried out in the Cochrane Database of Systematic Reviews, the Cochrane Library of Controlled Clinical Trials and Medline and Embase on the Dialog-Datastar platform. The controlled terminology of the respective databases was used, and both MeSH and Emtree were analysed for relevant entry terms. The search strategies covered the last 3 years. An update search was carried out before the publication of this document. Other data sources were also consulted, such as the Database of Abstracts of Reviews of Effectiveness (DARE), as well as relevant reference lists from other guideline producers such as the National Institute for Clinical Excellence (NICE) and the American Urological Association (AUA).

Most reviewed studies are retrospective analyses that include some larger multicentre studies and well-designed controlled studies. As only a few randomised controlled trials are available, there is a certain lack of data with a strong evidence base. Conversely, in the systemic treatment of metastasised RCC, a number of randomised studies have been performed, resulting in highly evidence-based recommendations.

1.3 Level of evidence and grade of recommendation

References in the text have been assessed according to their level of scientific evidence (Table 2), and guideline recommendations have been graded (Table 3) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (3). Grading aims to provide transparency between the underlying evidence and the recommendation given.

Table 2: Level of evidence*

<table>
<thead>
<tr>
<th>Level</th>
<th>Type of evidence</th>

</tr>
<tr>
<td>4</td>
<td>Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.</td>
</tr>
</tbody>
</table>

* Adapted from (3).

It should be noted that when recommendations are graded, the link between the level of evidence (LE) and the grade of recommendation (GR) is not directly linear. The availability of randomised controlled trials (RCTs) may not necessarily translate into a grade A recommendation when there are methodological limitations or disparities in the published results.

Conversely, an absence of a high level of evidence does not necessarily preclude a grade A recommendation if there is overwhelming clinical experience and consensus. There may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons, and in this case unequivocal recommendations are considered helpful. Whenever this occurs, it is indicated in the text as “upgraded based on panel consensus.” The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences, and costs when a grade is assigned (4-6).

The EAU Guidelines Office does not perform structured cost assessments, nor can it address local/ national preferences in a systematic fashion. But whenever these data are available, the expert panel will include the information.
### Table 3: Grade of recommendation*

<table>

### 1.4 Publication history

The EAU Renal Cell Cancer Guidelines were first published in 2000, with subsequent updates in 2001 (limited update), 2002 (limited update), and 2006 (full update), and partial updates in 2007, 2008, 2009, and 2010. This current 2013 printing presents a full-text update.

A quick reference guide presenting the main findings of the Renal Cell Cancer Guidelines is also available (Pocket Guidelines), as well as a number of scientific publications in the EAU journal, European Urology (7-9). All of the texts can be viewed and downloaded for personal use at the society’s web site: [http://www.uroweb.org/guidelines/online-guidelines/](http://www.uroweb.org/guidelines/).

The RCC panel recognises that there is a constant need to reevaluate the published evidence for this particular topic, but the next update, scheduled for 2014, will focus on covering sections with systematic reviews that could not be completed for the current printing.

### 1.5 Future goals

In addition to the systematic review, a number of other goals need to be taken into account. These include patient-derived needs, as well as recommendations requested by the ordinary urologist. We will be introducing such thoughts in the coming updates.

### 1.6 Potential conflict of interest statement

The members of the expert panel have submitted potential conflict of interest statements, which can be viewed on the EAU web site: [http://www.uroweb.org/guidelines/](http://www.uroweb.org/guidelines/).

### 1.5 References

2. EPIDEMIOLOGY AND ETIOLOGY

Renal cell carcinoma (RCC) represents 2-3% of all cancers with an age-standardised rate incidence of 5.8 and mortality of 1.4 per 100,000, respectively, in more developed areas (1). The highest incidence all over the world is in the Czech Republic, where in 2010 the incidence rate was 14.62 and mortality 5.17 (age-standardised rate/world per 100,000) (2).

Generally, during the last two decades and until recently, there has been an annual increase of about 2% in the incidence both worldwide and in Europe, although in Denmark and Sweden a continuing decrease has been observed (3). In 2008, it was estimated that there were 88,400 new cases of RCC and 39,300 kidney cancer-related deaths in the European Union (4). In Europe, the overall mortality rates for RCC increased up until the early 1990s, with rates generally stabilising in the following years, but increasing again in recent years (5). There has been a decrease in the mortality since the 1980s in Scandinavian countries and since the early 1990s in France, Germany, Austria, the Netherlands, and Italy. However, in some European countries (Croatia, Estonia, Greece, Ireland, Slovakia), the mortality rates are still showing an upward trend, with increasing rates (5). The mortality rate in Europe is 14,500 in females and 24,800 in males (both sexes 39,300) (4).

Renal cell carcinoma is the commonest solid lesion in the kidney and accounts for approximately 90% of all kidney malignancies. It includes different types, with specific histopathological and genetic characteristics (6). There is a 1.5:1.0 predominance of men over women, with the peak incidence occurring between the ages of 60 and 70. Etiological factors include lifestyle factors such as smoking, obesity, and hypertension (7-11). Obesity is a controversial issue, as there have been reports showing a better prognosis for obese patients suffering from renal cell cancer (12) Having a first-degree relative with kidney cancer is also associated with an increased risk of RCC (13,14). The most effective prophylaxis is to avoid cigarette smoking and obesity.

As tumours are detected more frequently using imaging techniques such as ultrasound and computed tomography (CT), the numbers of RCCs diagnosed incidentally has increased. These tumours are more often smaller and at a lower stage (15-17).

2.1 Conclusion

Several verified risk factors have been identified, including smoking, obesity, and hypertension. Cigarette smoking is a definite risk factor for RCC (LE: 2a).

2.2 Recommendation

| The most important methods for primary prevention of RCC are to eliminate cigarette smoking and avoid obesity. | B |

2.3 References

3. DIAGNOSIS AND STAGING

3.1 Symptoms

Many renal masses remain asymptomatic until the late stages of the disease. Currently, more than 50% of RCCs are detected incidentally when non-invasive imaging is used to investigate a variety of nonspecific symptoms and other abdominal diseases (1,2) (LE: 3). The classic triad of flank pain, gross haematuria, and palpable abdominal mass is now rare (6-10%) and correlates with aggressive histology and advanced disease (3,4) (LE: 3). Paraneoplastic syndromes are found in approximately 30% of patients with symptomatic RCCs (Table 4) (LE: 4). A few symptomatic patients present with symptoms caused by metastatic disease, such as bone pain or persistent cough (5) (LE: 3).
Table 4. Most common paraneoplastic syndromes

- Hypertension
- Cachexia
- Weight loss
- Pyrexia
- Neuromyopathy
- Amyloidosis
- Elevated erythrocyte sedimentation rate
- Anemia
- Abnormal liver function
- Hypercalcemia
- Polycythemia

3.1.1 Physical examination
Physical examination has only a limited role in the diagnosis of RCC. However, the following findings should prompt radiological examinations:
- Palpable abdominal mass;
- Palpable cervical lymphadenopathy;
- Nonreducing varicocele and bilateral lower extremity edema, that suggest venous involvement.

3.1.2 Laboratory findings
The most commonly assessed laboratory parameters are serum creatinine, glomerular filtration rate (GFR), complete cell blood count, erythrocyte sedimentation rate, liver function study, alkaline phosphatase, lactate dehydrogenase (LDH), serum corrected calcium, coagulation study, and urinalysis.

If there are central renal masses abutting or invading the collecting system, urinary cytology and possibly endoscopic assessment of the upper urinary tract should be considered in order to rule out the presence of urothelial cancer.

Split renal function should be estimated using renal scintigraphy in the following situations:
- When renal function is compromised, as indicated by an increased concentration of serum creatinine or a significantly decreased GFR.
- When renal function is clinically important - e.g., in patients with a solitary kidney or multiple or bilateral tumours (as in the hereditary forms of RCC).

Renal scintigraphy is an additional diagnostic option in patients who are at risk of future renal impairment due to comorbid disorders - e.g., diabetes, severe hypertension, chronic pyelonephritis, renovascular disease, urinary stones, or renal polycystic disease.

3.2 Imaging investigations
Most renal tumours are diagnosed when abdominal ultrasonography (US) or computed tomography (CT) are carried out for other medical reasons. Renal masses can be classified as solid or cystic on the basis of the imaging findings.

3.2.1 Presence of enhancement
With solid renal masses, the most important criterion for differentiating malignant lesions is the presence of enhancement. The traditional approach for detecting and characterising renal masses is to use US, CT, or magnetic resonance imaging (MRI). Most renal masses can be diagnosed accurately using imaging alone. Contrast-enhanced US can be helpful in specific cases (e.g., chronic renal failure with a relative contraindication for iodinated or gadolinium contrast media, complex cystic masses, and differential diagnosis of peripheral vascular disorders such as infarction and cortical necrosis).

3.2.2 CT or MRI
Computed tomography or MRI are used to characterise a renal mass. Imaging must be performed both before and after administration of intravenous contrast material in order to demonstrate enhancement. In CT imaging, enhancement in renal masses is determined by comparing Hounsfield unit (HU) readings before and after contrast administration. A change of 15 Hounsfield units or more is evidence of enhancement. To maximise differential diagnosis and detection, the evaluation should include images from the nephrographic phase, as this phase provides the best depiction of renal masses, which typically do not enhance to the same degree as the renal parenchyma.
CT or MRI allow accurate diagnosis of RCC in most cases. However, CT and MRI features cannot reliably distinguish oncocytoma and fat-free angiomyolipoma from malignant renal neoplasms (15-18) (LE: 3).

Abdominal CT provides information on:
- Function and morphology of the contralateral kidney (19) (LE: 3);
- Primary tumour extension (extrarenal spread);
- Venous involvement;
- Enlargement of locoregional lymph nodes;
- Condition of the adrenal glands and liver (LE: 3).

Abdominal contrast-enhanced biphasic CT angiography is a useful tool in selected cases to obtain detailed information about the renal vascular supply (e.g., for segmental renal artery clamping during partial nephrectomy) (20,21). If the patient is allergic to CT contrast medium, MRI biphasic angiography (MRA) may be indicated, but this is less sensitive and accurate than CT angiography for detecting supernumerary vessels (22). If the results of CT are indeterminate, MRI may provide additional information in order to:
- Demonstrate enhancement in renal masses (including solid enhancing nodular components in complex cystic masses) (23);
- Investigate locally advanced malignancy (24-26);
- Investigate venous involvement if the extent of an inferior vena cava tumour thrombus is poorly defined on CT scanning (24-27) (LE: 3). Doppler US is less accurate for identification of the extent of a venous tumour thrombus (26) (LE: 3).

MRI is indicated in patients who are allergic to intravenous CT contrast medium and in pregnancy without renal failure (25,28) (LE: 3). Advanced MRI techniques such as diffusion-weighted and perfusion-weighted imaging are being explored in the assessment of renal masses (29).

3.2.3 Other investigations
Renal arteriography and inferior venacavography only have a limited role in the work-up of selected patients with RCC (LE: 3). In patients with any sign of impaired renal function, an isotope renogram and total renal function evaluation should be considered in order to optimise treatment decision-making - e.g., the need to preserve renal function (8,9) (LE: 2a).

The true value of positron-emission tomography (PET) in the diagnosis and follow-up of RCC remains to be determined, and PET is not currently a standard investigation (30) (LE: 3).

3.2.4 Radiographic investigations for metastatic RCC
Chest CT is the most accurate investigation for chest staging (31-35) (LE: 3). However, at the very least, routine chest radiography must be performed for metastatic evaluation, as a less accurate alternative to chest CT (LE: 3). There is a consensus that most bone and brain metastases are symptomatic at diagnosis, so that routine bone or brain imaging is not generally indicated (31,36,37) (LE: 3). However, bone scan, brain CT, or MRI may be used in presence of specific clinical or laboratory signs and symptoms (37-39) (LE: 3).

3.2.5 Bosniak classification of renal cystic masses
For the evaluation of renal cystic masses, the Bosniak classification classifies renal cysts into five categories based on their CT imaging appearance, in an attempt to predict the risk of malignancy (40,41) (LE: 3). The Bosniak system also advocates treatment for each category (Table 5).
Table 5: The Bosniak classification of renal cysts (40)

3.3 Renal tumour biopsy (42-111)

Percutaneous renal tumour biopsies are increasingly being used: 1, for histological diagnosis of radiologically indeterminate renal masses; 2, to select patients with small renal masses for surveillance approaches; 3, to obtain histology before ablative treatments; 4, to select the most suitable form of targeted pharmacologic therapy in the setting of metastatic disease (42-51) (LE: 3).

Percutaneous sampling of a renal mass can be carried out using needle core biopsy and/or fine-needle aspiration (FNA). The aim is to determine malignancy, histological type, and grade of the renal tumour evaluated.

Due to the high diagnostic accuracy of current abdominal imaging findings, renal tumour biopsy is not necessary before surgical treatment in fit patients with a long life expectancy and a clearly suspicious, contrast-enhancing renal mass at abdominal CT or MRI (LE: 4).

Percutaneous sampling of renal masses can be performed under local anesthesia in the majority of cases (42-51) (LE: 3). Depending on the tumour’s location, its echogenic features, and the patient’s physical characteristics, biopsies can be performed with either ultrasound or CT guidance, with a similar diagnostic yield (47,50) (LE: 2b).

There is currently agreement that 18-gauge needles are ideal for renal tumour core biopsies, as they are associated with low morbidity and provide sufficient tissue for diagnosis in the majority of cases (42-50,52) (LE: 2b). A coaxial technique that allows multiple biopsies to be performed through a coaxial guide or cannula should always be used, in order to avoid the potential risk of tumour seeding (42-50) (LE: 3). With the use of coaxial techniques, no cases of seeding of renal tumours have been reported in recent years (42-50).

Overall, percutaneous biopsies have low morbidity. Spontaneously resolving subcapsular/perinephric haematoma and haematuria are the most frequently reported complications, while clinically significant bleeding is unusual (0-1.4%) and generally self-limiting (42-111).

Needle core biopsies are preferable for solid renal masses, as they have a greater diagnostic yield and better accuracy for diagnosing malignancy and histological type in comparison with FNA (44,47,49,53-55) (LE: 2b). Larger tumour size and solid pattern are predictors of a diagnostic core biopsy (47,50) (LE: 2b).

The ideal number and location of core biopsies have not been defined. However, at least two good-
quality cores (nonfragmented, > 10 mm in length) should be obtained, and necrotic areas should be avoided in order to maximize the diagnostic yield (42,44,47,48,50) (LE: 4). Peripheral biopsies are preferable for larger tumours, to avoid areas of central necrosis (56) (LE: 2b).

In recent series from experienced centers, core biopsies of solid renal tumours have shown a diagnostic yield of 78-97%, high specificity (98-100%), and high sensitivity (86-100%) for the diagnosis of malignancy (42-50,54,55,57-75) (LE: 2b). However, it should be noted that 2.5-22% of core biopsies are nondiagnostic (42-50,54,55,57-75) (LE: 2b). If a biopsy is nondiagnostic, but there are radiologic findings suspicious for malignancy, a further biopsy or surgical exploration should always be considered (LE: 4).

Assessment of tumour grade on core biopsies is challenging. The accuracy of Fuhrman grading on biopsies is poor (43-75%), but it can be improved using a simplified two-tier system (high-grade vs. low grade) (42-50,54,55,57-75) (LE: 2b). Core biopsies have a low diagnostic yield for cystic renal masses and should not be recommended alone in these cases, unless areas with a solid pattern are present (Bosniak IV cysts) (47,50) (LE: 2b). Combined FNA and core biopsies can provide complementary results, especially for complex cystic lesions (49,55,57,58,76,77) (LE: 3).

### 3.4 Histological diagnosis

The histological diagnosis of RCC is established after surgical removal of renal tumours with radical or partial nephrectomy or after percutaneous biopsy. According to the World Health Organization (112), there are three major histological subtypes of RCC:

- **Clear cell** (cRCC, 80-90%)
- **Papillary** (pRCC, 10-15%)
- **Chromophobe** (chRCC, 4-5%)

These RCC types can be differentiated on the basis of histological and genetic features (110) (LE: 3) (Table 6). Papillary RCC can be further divided into two different subtypes, type 1 and type 2 (Table 6) (113,114) (LE: 3).

#### Table 6: Major histological subtypes of RCC

<table>
<thead>
<tr>
<th>Histological subtype</th>
<th>Percentage of RCC</th>
<th>Histological description</th>
<th>Associated genetic changes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Clear cell (cRCC)</td>
<td>80-90%</td>
<td>Most cRCC are composed predominantly of cells containing clear cytoplasm, although eosinophilic cytoplasm predominates in some cells. The growth pattern may be solid, tubular, and cystic.</td>
<td>Identified by the specific deletion of chromosome 3p and mutation of the VHL gene. Other changes are duplication of the chromosome band 5q22, deletion of chromosome 6q, 8p, 9p, and 14q.</td>
</tr>
<tr>
<td>Papillary (pRCC)</td>
<td>10-15%</td>
<td>Most pRCCs have small cells with scanty cytoplasm, but also basophilic, eosinophilic, or pail-staining characteristics. A papillary growth pattern predominates, although there may be tubular papillary and solid architectures. Necrotic areas are common. Papillary RCC can be divided into two different subtypes: type 1 with small cells and pale cytoplasm and type 2 with large cells and eosinophilic cytoplasm, the latter having a worse prognosis.</td>
<td>The most consistent genetic alterations are trisomies of chromosomes 3q, 7, 8, 12, 16, 17, and loss of the y chromosome.</td>
</tr>
<tr>
<td>Chromophobe (chRCC)</td>
<td>4-5%</td>
<td>The cells of chRCC may have pall or eosinophilic granular cytoplasm. Growth usually occurs in solid sheets.</td>
<td>The genetic characteristic is a combination of loss of chromosomes 1, 2, 6, 10, 13, and 17.</td>
</tr>
</tbody>
</table>

### 3.5 Conclusions

- The incidence of small and incidental renal tumours has significantly increased in recent decades, but a proportion of patients with RCC still present with a palpable mass, haematuria, and paraneoplastic
and metastatic symptoms (LE: 3). Appropriate staging of RCC requires abdominal CT or MRI and chest imaging (LE: 3). Chest CT is the most sensitive approach for detecting lung metastases, but at least a chest radiograph should be performed for chest staging. There is no role for routine bone scanning or brain CT or MRI in the standard clinical work-up of asymptomatic patients.

- Percutaneous renal tumour biopsies are increasingly being used: 1, to establish the diagnosis of radiologically indeterminate renal masses; 2, to obtain histology of incidentally detected renal masses in patients who are candidates for nonsurgical treatment (active surveillance, ablative therapies); and 3, to select the most suitable targeted therapy for metastatic renal tumours.

### 3.6 Recommendations

4. CLASSIFICATION AND PROGNOSTIC FACTORS

4.1 Classification
The TNM classification system is generally recommended for clinical and scientific use (1). However, the system requires continuous improvements (2). The latest version of the TNM classification was published in 2010 (Table 7). The prognostic value of the 2010 TNM classification has been confirmed in both single and multi-institution studies (3,4). However, some uncertainties remain:
- The sub-classification of T1 tumours using a cut-off of 4 cm might not be optimal with the widening of nephron-sparing surgery for localised cancer.
- The value of size stratification of T2 tumours has been questioned (5).
- Since the 2002 version of the TNM classification, tumours with renal sinus fat invasion have been classified as pT3a. However, accumulating data suggest that renal sinus fat invasion carries a worse prognosis than perinephric fat invasion and therefore should not be included in the same pT3a stage group (LE: 3) (6-8).
- Some substages of the classification (pT2b, pT3a, pT3c and pT4) may overlap (4).
- The accuracy of the N1-N2 sub-classification has been questioned (9) (LE: 3). For adequate M staging...
of patients with RCC, accurate preoperative imaging (currently, chest and abdominal CT) should be performed (10,11) (LE: 4).

4.2 Prognostic factors
Factors influencing prognosis can be classified into: anatomical, histological, clinical, and molecular.

4.2.1 Anatomical factors
Anatomical factors include tumour size, venous invasion, renal capsule invasion, adrenal involvement, and lymph node and distant metastasis. These factors are commonly gathered together in the universally used TNM classification system (Table 7).

A help desk for specific questions about TNM classification is available at http://www.uicc.org/tnm.

4.2.2 Histological factors
Histological factors include Fuhrman grade, RCC subtype, sarcomatoid features, microvascular invasion, tumour necrosis, and invasion of the collecting system. Fuhrman nuclear grade is the most widely accepted histological grading system in RCC (12). Although affected by intra- and inter-observer discrepancies, it is an independent prognostic factor (13). It has been suggested that a simplified two- or three-strata Fuhrman grading system could be as accurate as the classical four-tiered grading scheme (14,15) (LE: 3).

According to the WHO classification (16), three major histological subtypes of RCC exist: conventional (clear cell) (80-90%); papillary (10-15%); and chromophobe (4-5%). In univariate analysis, there is a trend towards a better prognosis for patients with chromophobe versus papillary versus conventional (clear cell) RCC.
(17,18). However, the prognostic information provided by the RCC subtype is lost when stratified to tumour stage (18,19) (LE: 3).

Among papillary RCCs, two subgroups with different outcomes have been identified (20): Type 1 are low-grade tumours with a chromophilic cytoplasm and a favourable prognosis. Type 2 are mostly high-grade tumours with an eosinophilic cytoplasm and a great propensity for developing metastases (LE: 3).

RCC with Xp 11.2 translocation has been associated with a poor prognosis (21). Its incidence is low but should be systematically addressed in young patients.

The RCC type classification has been confirmed at the molecular level by cytogenetic and genetic analyses (22-24) (LE: 2b).

4.2.3 Clinical factors
Clinical factors include patient performance status, localised symptoms, cachexia, anaemia, and platelet count (25-28) (LE: 3).

4.2.4 Molecular factors
Numerous molecular markers being investigated, including: carbonic anhydrase IX (CaIX), vascular endothelial growth factor (VEGF), hypoxia-inducible factor (HIF), Ki67 (proliferation), p53, PTEN (phosphatase and tensin homolog) (cell cycle), E-cadherin, C-reactive protein (CRP), osteopontin (29) and CD44 (cell adhesion) (30,31) (LE: 3). To date, none of these markers has been shown to improve the predictive accuracy of current prognostic systems and their use is therefore not recommended in routine practice. Finally, even though gene expression profiling seems a promising method, it has not helped so far to identify new relevant prognostic factors (32).

4.2.5 Prognostic systems and nomograms
Postoperative prognostic systems and nomograms that combine independent prognostic factors have been developed and externally validated (33-39). These systems may be more accurate than TNM stage or Fuhrman grade alone for predicting survival (LE: 3). An important advantage of nomograms is their ability to measure predictive accuracy (PA), which enables all new predictive parameters to be objectively evaluated. Before being adopted, every new prognostic variable or system should be able to demonstrate that its PA is superior to conventional postoperative histo-prognostic schemes (40). Recently, new preoperative nomograms with excellent PAs have been designed (41,42). Table 8 summarises the current most relevant prognostic systems.

4.3 Conclusions

<table>
<thead>
<tr>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
</tr>
</tbody>
</table>

In patients with RCC, TNM stage, nuclear grade according to Fuhrman, and RCC subtype (WHO, 2004; [21]), should be performed because they contribute important prognostic information.

Prognostic systems should currently be used in a metastatic setting and are still investigational in localised disease.

4.4 Recommendations

<table>
<thead>
<tr>
<th>GR</th>
</tr>
</thead>
<tbody>
<tr>
<td>B</td>
</tr>
</tbody>
</table>

The current TNM classification system is recommended because it has consequences for prognosis and therapy.

The Fuhrman grading system and classification of RCC subtype should be used.

A stratification system should be used in a metastatic setting for selecting the appropriate first-line treatment.

In localised disease, the use of integrated prognostic systems or nomograms is not routinely recommended, even though these systems can provide a rationale for enrolling patients into clinical trials.

No molecular prognostic marker is currently recommended for routine clinical use.

5. OTHER RENAL TUMOURS

Detailed morphological studies, which use contemporary immunohistochemical and molecular techniques, have resulted in the current classification of renal epithelial neoplasms, as outlined in the 2004 WHO monograph (1). A revised histopathological classification is expected in 2013. The common clear cell renal carcinoma (cRCC), papillary RCC (pRCC) and chromophobe RCC (chRCC) types account for 85-90% of renal malignancies. The remaining 10-15% of renal tumours includes a variety of uncommon, sporadic, and familial carcinomas, some of which have recently been described, and a group of unclassified carcinomas.

5.1 Bellini duct carcinoma (collecting-duct carcinoma)
Collecting-duct carcinoma is a very rare type of RCC, often presenting at an advanced stage of disease. Up to 40% of patients have metastatic spread at initial presentation and most patients die within 1-3 years from the time of primary diagnosis. The hazard ratio in cancer specific survival is in comparison with cRCC 4.49 (2). To date, the largest case series (n = 81) to consider outcome showed that regional lymph node metastases were present in 44% of patients at diagnosis and distant metastases were present in 32%. The survival rate was 48% at 5 years and 14% at 10 years (3-5). Median survival was 30 months (6). Response to targeted therapies was poor (7).

5.2 Renal medullary carcinoma
Renal medullary carcinoma is a devastating malignancy that primarily affects young black men with sickle cell trait. However, case reports in white and Hispanic patients without sickle cell trait have emerged (3). Renal medullary carcinoma is considered to be a subtype of collecting duct carcinoma (8). It is extremely rare; comprising approximately 2% of all primary renal tumours in young people aged 10 to 20 years. Metastatic disease is seen at presentation in 95% of patients (3,9,10). Median survival is 5 months (6). Surgical intervention alone is inadequate (9), systemic therapy is not defined, different regimes of chemotherapy are used, and the tumour is radiosensitive. Due to the rarity of this tumour type, it is unlikely that a randomised trial can be carried out in a timely fashion (11).

5.3 Sarcomatoid RCC
Sarcomatoid RCC represents high-grade transformation in different RCC types, without being a distinct histological entity. Sarcomatoid changes in RCC carry a worse prognosis (12). The hazard ratio in cancer specific survival is in comparison with cRCC (2). Metastatic sarcomatoid RCC is associated with a poor response to systemic therapy. Sunitinib treatment resulted in a modest response rate (13). The combination of gemcitabine and doxorubicin could also be an option (14). (LE: 3) (GR: C).
5.4 Unclassified RCC
Unclassified RCC is a diagnostic category for RCC that cannot be assigned to any other category of RCC-type carcinoma (1).

5.5 Multilocular cystic RCC
There are no strict histopathological criteria for this subtype. In the WHO 2004 classification (1), multilocular cystic RCC is an independent entity, but it is essentially a well-differentiated clear cell RCC (15). This subtype accounts for up to approximately 3.5% of surgically treated kidney tumours (16). To date, metastases of this tumour have not been described (16,17). According to the Bosniak classification, which is based on imaging criteria, multilocular cystic RCC presents as a Bosniak type II or III cystic lesion (18-20). However, this type of Bosniak lesion can also be due to a mixed epithelial and stromal tumour of the kidney (MESTK), a cystic nephroma (both see section 5.11), or a multilocular cyst, all of which are benign lesions. In many cases, a pre-operative biopsy and intra-operative frozen-section analysis does not lead to a correct diagnosis. Fortunately, all these tumours are treated with the same operative strategy. For this reason, if technically feasible, a nephron-sparing procedure is the technique of choice for a complex multicystic renal mass when enhanced density is observed (LE: 3) (GR: B) (15-17,19,20).

5.6 Papillary adenoma
Papillary adenomas are tumours with papillary or tubular architecture of low nuclear grade and are 5 mm in diameter or smaller (1). Because they are so small, they are only found incidentally in a nephrectomy specimen.

5.7 Translocation carcinoma (MITF/TFE family translocation-associated carcinoma)
Renal translocation carcinomas are uncommon tumours, which usually occur in children and young adults. Most translocation carcinomas (about 90%) involve the transcription factor E3 (TFE3) located on Xp11.2 and seem to follow a relatively indolent course, despite often being at an advanced stage at presentation, however, the clinical course is most aggressive in adults (3). Basically, there are 2 well-defined subtypes (ASPL/TFE3 and PRCC/TFE3). VEGF-targeted agents appear to demonstrate some efficacy (21,22). Another rare group of RCCs that show a translocation [t(6; 11) (p21; q12)] has also been reported (3,23). A case report with a metastatic course and a partial response to sunitinib malate was described (24).

5.8 Mucinous tubular and spindle cell carcinoma
This tumour is associated with the loop of Henle. Most mucinous tubular and spindle-cell carcinomas behave in a low-grade fashion (1,3,25).

5.9 Carcinoma associated with end-stage renal disease
Acquired cystic disease-associated renal cell carcinoma, clear cell papillary RCC.
Cystic degenerative changes (acquired cystic kidney disease [ACKD]) and a higher incidence of RCC are typical features of ESKD (end-stage kidney disease). The incidence of ACKD is about 50% in patients undergoing dialysis, but also depends on the duration of dialysis, gender (three times more common in men), and the diagnostic criteria of the method of evaluation. RCCs of native end-stage kidneys are found in about 4% of patients. The lifetime risk of developing RCCs is at least 10 times higher than that in the general population. Compared with sporadic RCCs, the RCCs associated with ESKD and ACKD are characterised by multicentricity and bilaterality, are found in younger patients (mostly male), and have a less aggressive behaviour (26, 27). A relatively indolent outcome of tumours in ESKD is due only to the mode of diagnosis and not to specific ESKD-related molecular pathways still to be determined (27). RCC arising in native kidneys of transplant patients seems to exhibit many favourable clinical, pathological and outcome features compared with those diagnosed in dialysis-only patients. Further research is needed to determine whether this is due to particular molecular pathways or to biases in relation to mode of diagnosis (28). Although the histological spectrum of tumours within ACKD is similar to that in sporadic RCC, the most predominant form is pRCC, being found in 41-71% of ACKD-associated RCC versus 10% in sporadic RCC. The remaining tumours are mostly cRCC (3,26,27). Tickoo et al. (29) described two new renal tumours associated with ESKD: ‘acquired cystic disease-associated RCC’ and ‘clear-cell pRCC’. To date, these two entities are under conscientious discussion. Clear cell (tubulo) pRCC has been reported in otherwise normal kidneys as well, and has low potential for malignancy (30,31). The existence of ACKD-associated RCC is in dispute (27). Patients with ESKD should undergo an annual ultrasound evaluation of the kidneys. Minimally invasive radical nephrectomy can be performed safely in these patients (32).

5.10 Metanephric tumours
Metanephric tumours are divided into metanephric adenoma, adenofibroma, and metanephric stromal tumour. These are very rare benign tumours and surgical excision is sufficient (1).
5.11 Renal epithelial and stromal tumours
Renal epithelial and stromal tumours (REST) is a new concept that brings together two benign mixed mesenchymal and epithelial tumours: cystic nephroma and mixed epithelial and stromal tumours (33). Imaging studies have revealed that most REST cystic lesions are Bosniak type III and less frequently Bosniak type II or IV (18,20). Although aggressive behaviour has been reported in very few cases, both neoplasms are generally considered to be benign and surgical excision is curative (33).

5.12 Oncocytoma
Renal oncocytomas are benign tumours (1) that comprise about 3-7% of all renal tumours (34). Imaging characteristics alone are unreliable when differentiating between oncocytoma and RCC. Histopathological diagnosis remains the reference standard (35,36). Although only a percutaneous biopsy can lead to a preoperative diagnosis, it has a low specificity for oncocytoma because oncocytotic cells are also found in cRCC, (the granular-cell variant of RCC), and in the eosinophilic variant of pRCC (type 2) and the oncocytic variant of pRCC. ‘Watchful waiting’ can be considered in selected cases of histologically verified oncocytoma. Alternative management includes partial nephrectomy and minimally invasive approaches. (LE: 3) (GR: C) (37,38).

5.13 Hereditary kidney tumours
Hereditary kidney tumours can be found as part of the following entities: Von Hippel-Lindau syndrome, hereditary pRCC, Birt-Hogg-Dubé syndrome (see Hybrid oncocytoma-chromophobe carcinoma), hereditary leiomyomatosis and renal cell cancer (HLRCC), tuberous sclerosis, and constitutional chromosome 3 translocation (1,39).

5.14 Mesenchymal tumours
Mesenchymal tumours include different types of benign tumours and sarcomas and are relatively rare, except for angiomyolipoma.

5.14.1 Angiomyolipoma
Angiomyolipoma (AML) is a benign mesenchymal tumour composed of a variable proportion of adipose tissue, spindle and epithelioid smooth muscle cells, and abnormal thick-walled blood vessels. It can occur sporadically, and is four times more likely in women. It also occurs in tuberous sclerosis (TS), when it is multiple, bilateral, larger, and likely to cause spontaneous haemorrhage. It accounts for approximately 1% of surgically removed tumours. Ultrasound, CT, and MRI often lead to diagnosis due to the presence of adipose tissue. Biopsy is rarely useful. Pre-operatively, it may be difficult to differentiate between tumours composed predominantly of smooth muscle cells and epithelial tumours. AML can be found in TS in lymph nodes, but it is not metastatic disease, but disease with a multicentric genesis. AML can be due to angiotropic-type growth involved in the renal vein even the inferior vena cava. AML with involvement of lymph nodes and tumorous thrombus is benign. Only epithelioid AML is a potentially malignant variant of AML (1,40). AML is associated with a slow and consistent growth rate (0.088 cm/year), and typically has minimal morbidity (41). The main complications of renal AML are retroperitoneal bleeding or bleeding into the urinary collection system, which may be life-threatening (42). The bleeding tendency is related to the angiogenic component of the tumour that includes irregular and aneurysmatic blood vessels (42). The major risk factors for bleeding are tumour size, grade of the angiogenic component of the tumour, and the presence of tuberous sclerosis (42,43). Primary indications for intervention include symptoms such as pain, bleeding, or suspected malignancy.

Prophylactic intervention is justified for:
• large tumours (the recommended threshold of intervention does not exist, the formerly recommended size of > (3) 4 cm wide is disputed) (41,42,44);
• females of childbearing age;
• patients in whom follow-up or access to emergency care may be inadequate (43) (LE: 3) (GR: C).

Most cases of AML can be managed by conservative nephron-sparing approaches, although some cases of AML may require complete nephrectomy (43) (LE: 3). Of the standard surgical interventions, selective arterial embolisation (SAE) and radiofrequency ablation (RFA) can be used (41,42,44). Although SAE is effective at controlling haemorrhage in the acute setting, it has limited value in the longer-term management of AML (45). Clinical trials of medical management with m-TOR inhibitors are ongoing (46) and sirolimus can be combined with deferred surgery (47).

5.15 New histological entities
New histological entities have recently been described, for which there currently is very little clinical data. Some
of these entities are supposed to be included in a new ongoing histopathological classification. These entities include:

- **Hybrid oncocytoma-chromophobe RCC**
  Hybrid oncocytic/chromophobe tumours (HOCT) of the kidney have been described for the first time in patients with Birt-Hogg-Dubé syndrome (a rare autosomal dominant syndrome characterised by skin hamartomas and multiple renal tumours) in association with renal oncocytoysis. A sporadic variant also exists. The tumours seem to behave indolently as no evidence of malignant behaviour has been documented to date. However, these tumours could have a low malignant potential and patients should be followed-up as chromophobe RCC (48,49).

- **Oncocytic papillary renal cell carcinoma - type 3**
  This tumour could be termed a pRCC type 3. In comparison with pRCC type I and II, it has no pseudocapsule, no massive necroses, and extrarenal growth is relatively rare. The malignant potential is low (50).

- **Tubulocystic renal cell carcinoma (TCRCC)**
  This occurs predominantly in men over a wide age range. There is a possible relationship to pRCC. It frequently displays a cystic component which may result in a radiological classification of Bosniak III or IV. TCRCC has definite malignant potential (51).

- **Thyroid-like follicular carcinoma of the kidney**; rare tumour closely mimicking well-differentiated thyroid follicular neoplasms.

- **RCC associated with neuroblastoma**; extremely rare, morphologically heterogeneous entity.

- **Renal angiomyoadenomatous tumour**; the relation with clear cell pRCC (see above 5.9) is discussed (30,31,54).

### 5.16 Summary

A variety of renal tumours exists, of which about 15% are benign. All kidney lesions have to be examined (e.g. imaging, biopsy, etc.) and judged regarding the likelihood of malignant behaviour.

6. TREATMENT OF LOCALISED RCC AND LOCAL TREATMENT OF METASTATIC RCC

A systematic review underpins the findings of sections 6.1 – 6.2. This review included all relevant published literature comparing surgical management of localised RCC (T1-2N0M0) (1,2). Randomised or quasi-randomised controlled trials (RCTs) were included. However, due to the very limited number of RCTs, non-randomised studies (NRS), prospective observational studies with controls, retrospective matched-pair studies, and comparative studies from well-defined registries databases were also included. Studies with no comparator group (for example, case series), unmatched retrospective studies, and chart reviews were excluded due to their inherent risk of selection bias. The systematic review methodology has been reported in detail elsewhere (1,2).

For sections 6.3 – 6.5, a traditional narrative review was performed (see Chapter 1).
For sections 6.6 – 6.7, a systematic review and narrative synthesis of the evidence was performed (see Chapter 1).

6.1 Main comparisons
6.1.1 Surgery versus non-surgical treatment
One matched pair study (derived from the SEER database) compared surgery for small renal masses (≤ 4 cm) with non-surgical management (3). Included were pT1a patients who were assigned to either observation or active surveillance. The analysis showed that surgical therapy had a significant 5 year cancer-specific mortality benefit over non-surgical intervention. However, even though this study was matched, it is marked by allocation bias; the patients assigned to the surveillance arm were older and likely more frail and less suitable candidates for surgery. There was no comparative study addressing this comparison in terms of perioperative and QoL outcomes.

6.1.2 Nephron-sparing surgery versus radical nephrectomy
Based on the available oncological and QoL outcomes, the current evidence suggests that localised renal cancers are best managed by nephron-sparing surgery (partial nephrectomy) rather than by radical nephrectomy, irrespective of the surgical approach.

When open partial nephrectomy was compared to open radical nephrectomy the estimated cancer-specific survival rates (CSS) at 5 years were comparable. (4-7). A number of studies compared partial against radical nephrectomy, either performed by an open or laparoscopic approach for renal carcinoma (≤ 4 cm) (8-11). These studies showed that radical nephrectomy was associated with increased mortality from any cause after adjusting for patient characteristics. In studies analysing RCCs 4-7 cm no differences were shown...
for CSS between partial nephrectomy and radical nephrectomy (11-16). Also when laparoscopic partial nephrectomy and laparoscopic radical nephrectomy was compared in RCCs > 4 cm there was no difference in overall survival (OS), CSS and recurrence-free survival rates (RFS) (17).

In a number of studies various aspects of QoL and safety were compared for open partial and open radical nephrectomy (4-7,18-20). No difference in length of hospital stay (5,6,20), blood transfusions (5,18,20), or mean blood loss was found (5,20). In general, complication rates are inconsistently reported in NRS, and no clear conclusions in favour of one intervention over another can be drawn (21). The mean operative time was longer for the open partial group (20) but others found no such difference (22). Three studies consistently reported worse renal function after radical nephrectomy compared to partial nephrectomy (4,7,18). A greater proportion of patients had impaired postoperative renal function after radical nephrectomy after adjustment for diabetes, hypertension and age (7).

One database review compared open partial with laparoscopic radical nephrectomy in RCCs 4-7 cm (13). After partial nephrectomy, the mean increase of post-operative creatinine levels was significantly lower. When laparoscopic partial nephrectomy was compared to laparoscopic radical nephrectomy, the estimated GFR in the nephron-sparing group decreased less as compared to the radical nephrectomy group which showed a significantly greater proportion of patients with a 2-stage increase in the CKD stage (17). Another database review (23) compared laparoscopic partial with laparoscopic radical nephrectomy for RCCs > 4 cm in size. The laparoscopic radical nephrectomy group had a significantly greater decrease in estimated GFR and a greater proportion of patients with a CKD 2 stage.

Two studies reported QoL post-surgery for RCC. Patients who underwent partial nephrectomy reported better scores, in many aspects of quality of life (19). Those who underwent radical nephrectomy reported a higher degree of fear associated with living with only one kidney. Regardless of the intervention, patients with RCCs < 4 cm and a normal contralateral kidney showed the highest QoL scores after treatment, which matched their pre-diagnosis scores. Patients who had higher complications rates had lower QoL scores (5).

No comparative studies were identified reporting on oncological outcomes for minimally invasive ablative procedures compared with radical nephrectomy.

Patient and tumour characteristics permitting, the current oncological outcomes evidence base suggests that localised RCCs are best managed by NSS rather than by radical nephrectomy irrespective of surgical approach. Where open surgery is deemed necessary, the oncological outcomes following open NSS are at least as good as open radical nephrectomy and should be the preferred option when technically feasible. However, in some patients with localised RCC, NSS is not suitable because of:

- locally advanced tumour growth;
- partial resection is not technically feasible because the tumour is in an unfavourable location;
- significant deterioration of a patient’s general health.

In these situations, the curative therapy remains radical nephrectomy, which includes removal of the tumour-bearing kidney. Complete resection of the primary tumour by either open or laparoscopic surgery offers a reasonable chance of curing the disease.

6.1.3 Associated procedures

6.1.3.1 Adrenalectomy

One prospective NRS compared the outcomes of radical or partial nephrectomy with, or without, ipsilateral adrenalectomy (24). On multivariate analysis, upper pole location was not predictive of adrenal involvement but tumour size proved significant. There was no difference in overall survival (OS) at 5 or 10 years, with, or without, adrenalectomy. Adrenalectomy was justified using criteria, based on radiographic and intra-operative findings. Only 48 of 2,065 patients underwent concurrent ipsilateral adrenalectomy of which 42 were for benign lesions.

6.1.3.2 Lymph node dissection

An extended or radical lymph node dissection does not appear to improve long-term survival following tumour nephrectomy (25). Thus, for staging purposes, lymph node dissection can be limited to the hilar region. In patients with palpable or CT-detected enlarged lymph nodes, resection of the affected lymph nodes should be performed to obtain adequate staging information.

6.1.3.3 Embolisation

Before a routine nephrectomy, there is no benefit in performing tumour embolisation (26,27). In patients who are unfit for surgery, or who present with non-resectable disease, embolisation can control symptoms such as gross haematuria or flank pain (28-30). Embolisation prior to the resection of hypervascular bone or spinal metastases can reduce intra-operative blood loss (31). In selected patients with painful bone or paravertebral
metastases, embolisation can help to relieve symptoms (32).

### 6.2 Techniques of radical and partial nephrectomy

#### 6.2.1 Techniques of radical nephrectomy

There are no randomised studies assessing oncological outcomes of laparoscopic versus open radical nephrectomy. A prospective cohort study (33) and a retrospective database review (5), both of low methodological quality, found similar oncological outcomes for laparoscopic versus open radical nephrectomy. Data from one RCT (34) and two NRSs (5,33) showed significantly shorter hospital stay and lower analgesic requirement for the laparoscopic radical nephrectomy group compared with the open group. Convalescence time was also significantly shorter (33). There was no difference in number of patients receiving a blood transfusion between the approaches but the perioperative blood loss was significantly less in the laparoscopic arm in all three studies (5,33,34). Surgical complications were marked by low event rates and very wide confidence intervals. There was no difference in complications but the operation time was significantly shorter in the open arm. Post-operative QoL scores were similar between the two groups (5).

In regard to the approach of performing radical nephrectomy, both retroperitoneal or transperitoneal approaches had similar oncologic outcomes in two RTCs (35,36) and one quasi-randomised study (37). There was no significant difference in quality of life variables between the two approaches.

Hand-assisted laparoscopic radical nephrectomy and standard laparoscopic radical nephrectomy was compared in one RCT (37) and one database review (21). Estimated 5-year overall survival, cancer-specific survival, and recurrence free survival rates were comparable between the approaches. Duration of operation was significantly shorter in the hand-assisted compared to the laparoscopic approach but length of hospital stay and time to non-strenuous activities were shorter for standard laparoscopic radical nephrectomy (21,37). However, the sample size was small.

Robot-assisted laparoscopic radical nephrectomy versus laparoscopic radical nephrectomy was compared in one small prospective cohort study (38). There were no local recurrences, port-site or distant metastases, but sample size was small and follow-up was less than 1 year. Similar results were presented in observational cohort studies comparing ‘portless’ (n = 14) and 3-port (n = 15) laparoscopic radical nephrectomy (39,40). There was no difference in perioperative outcomes.

#### 6.2.2 Techniques of partial nephrectomy and minimally invasive ablative procedures

Laparoscopic partial nephrectomy compared to open partial nephrectomy showed no difference in overall survival (41-44). Regarding the number of deaths during the study period, a lower risk of all cause death was shown in the laparoscopic group in one study (42) while in other studies no difference in the recurrence patterns between laparoscopic and open partial nephrectomy was reported (41,44). In a matched pair analysis (43) the length of hospital stay was significantly shorter and there was less mean blood loss in the laparoscopic
partial group. In one database review more blood transfusion events occurred in the laparoscopic group (41). There were no differences between the groups in postoperative mortality events (41,43), DVT events (43), or pulmonary embolism events but the operative time was significantly longer in the laparoscopic partial group (22,43,44). Decline in GFR was greater in the laparoscopic partial nephrectomy group in the immediate postoperative period (44), but not after a follow-up of 3.6 years.

There is no comparative study that reported on oncological outcomes between robotic assisted partial nephrectomy and laparoscopic partial nephrectomy. One study based on a matched-pair analysis (45) showed no difference in perioperative outcomes (10) or in the estimated GFR.

In regard to partial nephrectomy versus minimally invasive ablative procedures, several studies were identified. For radiofrequency-assisted robotic partial nephrectomy versus laparoscopic partial nephrectomy, a database review (46) found no differences between the groups in terms of positive surgical margins and recurrence rates, but the study was marked by very low event rates, a high number of benign tumours, and short-term survival data.

Data on laparoscopic cryoablation versus laparoscopic partial nephrectomy obtained from one database review (47) reported 3 deaths out of 78 patients treated, compared with none out of 153 patients treated with laparoscopic partial nephrectomy. In another matched pair study no recurrences were reported in either treatment but with a follow-up of less than 12 months (48). It should be noted that the studies also included benign tumours and the data should be treated with caution. In a database review (47) and a matched-pair study (48) there were no differences in perioperative outcomes, recovery times, complication rates or postoperative serum creatinine levels between laparoscopic cryoablation and laparoscopic partial nephrectomy. Blood loss was less and surgical time was quicker in the cryoablation group than the laparoscopic partial nephrectomy group (47,48). In one matched comparison between laparoscopic cryoablation and open partial nephrectomy (49) no local recurrences or metastasis was found in either group. The length of hospital stay was shorter and the mean blood loss was significantly less in the laparoscopic cryoablation group, but there was no difference in number of patients requiring blood transfusions or duration of operation. However, there were only 20 patients in each arm and the follow-up time was short.

6.3 Therapeutic approaches as alternatives to surgery

6.3.1 Surveillance

Elderly and co-morbid patients with incidentally detected small renal masses have a relatively low RCC-specific mortality and a significant competing-cause mortality (50,51).

Active surveillance is defined as the initial monitoring of tumour size by serial abdominal imaging (ultrasound, CT, or MRI) with delayed intervention reserved for those tumours that show clinical progression during follow-up (52).

In the largest reported series of active surveillance the growth of renal tumours is low in the majority of
cases and progression to metastatic disease is reported in a limited number of patients (1-2%) (53,54). Both short- and intermediate-term oncological outcomes indicate that in selected patients with advanced age and/or comorbidities, active surveillance is an appropriate strategy to initially monitor small renal masses, followed if required by treatment for progression (52-58).

6.4 Adjuvant therapy
Current evidence that adjuvant tumour vaccination might improve the duration of the progression-free survival of selected subgroups of patients undergoing nephrectomy for T3 renal carcinomas needs further confirmation regarding the impact on overall survival (LE: 1b) (59-63). Prognostic algorithms might identify patients likely to derive the largest clinical benefit from adjuvant vaccination therapy.

6.5 Surgical treatment of metastatic RCC (tumour nephrectomy or cytoreductive nephrectomy)
Tumour nephrectomy is curative only if surgery can excise all tumour deposits. For the majority of patients with metastatic disease, cytoreductive nephrectomy is palliative and systemic treatments are necessary. In a meta-analysis of two randomized studies, comparing cytoreductive nephrectomy combined with immunotherapy versus immunotherapy only, an increased long-term survival was found in patients subjected to cytoreductive nephrectomy (64). At present, only limited data are available addressing the value of cytoreductive nephrectomy combined with targeting agents such as sunitinib, sorafenib and others. Randomised studies are ongoing.

6.6 Surgical resection of metastases in metastatic RCC
A systematic review was undertaken (65). No randomised trials were identified comparing metastasectomy with other treatments, but 12 non-randomised comparative studies involving metastasectomy were identified. A number of studies compared complete metastasectomy with partial metastasectomy in patients with metastatic RCC involving multiple organ sites (66-68). The results showed an overall survival advantage for complete resection. When complete metastasectomy was compared with no surgical resection (69-71), complete metastasectomy offered a slight overall survival advantage.

In the treatment of bone metastases, metastasectomy in combination with local stabilization provided a significant survival advantage over that of non-surgical treatment (72).
In visceral metastases affecting the liver and pancreas, metastasectomy showed a significantly prolonged overall survival compared with non-surgical treatment (73,74). For patients with liver metastases, radical resection was associated with significantly better overall survival compared with either partial resection or ablation (75).

For the treatment of brain lesions, one study compared metastasectomy followed by whole brain radiotherapy, against fractionated stereotactic radiotherapy or conventional radiotherapy alone (76). There was no difference in cancer specific survival, although surgery appeared to offer some benefits regarding local tumour control.

### 6.7 Radiotherapy for metastases in metastatic RCC

A systematic review was undertaken (65). Three non-randomised comparative studies involving different radiotherapy modalities were identified. The results showed there was no significant survival benefit using radiotherapy. However, there was evidence of improved local tumour control with radiotherapy. Two studies (77,78) involving bone metastases showed an improvement in bone pain using different radiotherapy modalities. In a study on brain metastases (79) whole brain radiotherapy alone, stereotactic radiosurgery alone or a combination of the two were compared. The study showed a good local tumour control using either individual modality in patients with 1-3 metastases to the brain.

### Conclusions

There is a definite role for metastasectomy in patients with RCC in order to improve the clinical prognosis. Its role has to be continuously re-evaluated, especially in combination with targeted systemic therapy.

### Recommendations

- In patients with metastatic spread, metastasectomy should be performed where disease is resectable and the patient has a good performance status. **C**
- Metastasectomy should be performed in patients with residual and resectable metastatic lesions previously responding to immunotherapy and/or other systemic treatment. **C**
- In individual cases, stereotactic radiotherapy for the treatment of bone and brain metastases can induce symptom relief. **C**

7. SYSTEMIC THERAPY FOR METASTATIC RCC

7.1 Chemotherapy

Since RCCs develop from the proximal tubules, they have high levels of expression of the multiple-drug resistance protein, P-glycoprotein, and are therefore resistant to most forms of chemotherapy. Chemotherapy appears to be moderately effective only if 5-fluorouracil (5-FU) is combined with immunotherapeutic agents (1). However, in a prospective randomised study, interferon-alpha (IFN-\(\alpha\)) showed equivalent efficacy to a combination of IFN-\(\alpha\) + interleukin-2 (IL-2) + 5-FU (2).

</tr>
</tbody>
</table>

7.2 Immunotherapy

7.2.1 Interferon alpha as monotherapy and combined with bevacizumab

Interferon alpha has been shown in randomised studies to be superior in relation to survival to hormonal therapy in patients with mRCC (3). IFN-\(\alpha\) provided a response rate of 6-15\%, together with a 25% decrease in the risk for tumour progression and a modest survival benefit of 3-5 months in comparison with a placebo equivalent (4,5).

The positive effect of IFN-\(\alpha\) is particularly apparent in mRCC patients with clear cell histology, good-risk Motzer criteria, and lung metastases only (5). In a prospective randomised study, IFN-\(\alpha\) showed equivalent efficacy to a combination of IFN-\(\alpha\) + IL2 + 5-FU (2). The moderate efficacy of immunotherapy was also confirmed in a Cochrane meta-analysis including 42 eligible studies (6).

A combination of bevacizumab + IFN-\(\alpha\) was recently shown to be associated with increased response rates and better progression-free survival in first-line therapy in comparison with IFN-\(\alpha\) monotherapy (7). All recent randomized studies comparing anti-angiogenic drugs in a first-line setting to IFN-\(\alpha\) monotherapy have shown superiority for either sunitinib, bevacizumab + IFN-\(\alpha\), or temsirolimus (7-10).

* Favourable (low) risk, no risk factors; intermediate risk, one or two risk factors; poor (high) risk, three or more risk factors.

7.2.2 Interleukin-2

Interleukin-2 (IL-2) has been used to treat mRCC since 1985, with response rates ranging from 7\% to 27\% (10-12). The optimal IL-2 regimen is not clear, but long-term (> 10 years) complete responses have been achieved.
with high-dose bolus IL-2 in a randomised phase III study (13). The toxicity of IL-2 is substantially greater than that of IFN-α. Only clear cell-type RCC responds to immunotherapy. Interleukin-2 has not been validated in controlled randomised studies in comparison with best supportive care (5).

7.2.3 Vaccines and targeted immunotherapy

No recommendations can be made. An earlier phase III trial of vaccine therapy with tumour antigen 5T4 in combination with the first-line standard of care (either sunitinib, interleukin-2, or interferon alpha) failed to demonstrate any survival benefit in comparison with placebo and the first-line standard of care (14). Several phase III vaccination studies are ongoing. Targeted immunotherapy with programmed death-1 ligand (PD-1L), which has shown efficacy and acceptable toxicity in patients with RCC (15), is currently under investigation in a phase II trial in comparison with everolimus in patients in whom anti-angiogenic therapy previously failed.

7.2.5 Recommendations

| GR       | Monotherapy with IFN-α or high-dose bolus IL-2 can only be recommended as a first-line treatment for mRCC in selected patients with clear cell histology and good prognostic factors. A |
| GR       | Bevacizumab + IFN-α is recommended as first-line therapy in low-risk and intermediate-risk patients. B |
| GR       | Only selected patients with mRCC who have a good risk profile and clear cell subtype histology show clinical benefit from immunotherapy with IL-2. |
| GR       | Cytokine combinations, with or without additional chemotherapy, do not improve the overall survival in comparison with monotherapy. A |

7.3 Drugs targeting VEGF, including other receptor kinases and mammalian target of rapamycin (mTOR)

Recent advances in molecular biology have led to the development of several novel agents for the treatment of mRCC (Table 11).

In sporadic clear cell RCC, hypoxia-inducible factor (HIF) accumulation due to von Hippel-Lindau (VHL) inactivation results in overexpression of vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF), both of which promote neoangiogenesis (16-18). This process substantially contributes to the development and progression of RCC. At present, several targeting drugs have been approved both in the USA and in Europe for the treatment of mRCC:

- Sorafenib (Nexavar®)
- Sunitinib (Sutent®)
- Bevacizumab (Avastin®) combined with IFN-α
- Pazopanib (Votrient®)
- Temsirolimus (Torisel®)
- Everolimus (Afinitor®)
- Axitinib (Inlyta®)

New agents targeting angiogenesis are under investigation, as well as combinations of these new agents with each other or with cytokines. One of the new agents targeting angiogenesis, tivozanib, has been investigated in a phase III trial and is currently not approved. Evidence-based data for this drug are presented below. Most published trials have selected for clear cell carcinoma subtypes, and consequently no evidence-based
recommendations can be given for non-clear cell subtypes.

In the major phase III trials leading to registration of the approved targeted agents, patients were stratified according to the Memorial Sloan-Kettering Cancer Center (MSKCC) risk model, as published in 2002 (3) (Table 10). Since the MSKCC criteria were established in the era of cytokines, an international database consortium has established and validated a risk model (the Database Consortium Model, DCM) which may yield a more accurate prognosis for patients treated in the era of targeted therapy. In the DCM, neutrophilia and thrombocytosis are added to the MSKCC risk factors. By contrast, lactate dehydrogenase (LDH) is omitted from the factors associated with the prognosis (19). The DCM has recently been used to establish data on conditional survival that can be used to counsel patients (20). The DCM has been validated and compared with the risk model of the Cleveland Clinic Foundation (CCF), the French model, MSKCC model, and the International Kidney Cancer Working Group (IKCWG) model. The DCM showed a concordance level of 0.66, which did not differ from the other models, indicating that a ceiling has been reached for clinical risk models for predicting the prognosis based solely on clinical factors. However, the reported versus predicted number of deaths at 2 years was most similar in the DCM in comparison with the other models (21). The DCM has been externally validated for use in the era of targeted therapy (21).

Table 11: Median overall survival and percentage of patients surviving 2 years treated in the era of targeted therapy per DCM risk group, based on the publications by Heng et al. (19,21)

7.3.1 Tyrosine kinase inhibitors

7.3.1.1 Sorafenib

Sorafenib is an oral multikinase inhibitor with activity against Raf-1 serine/threonine kinase, B-Raf, vascular endothelial growth factor receptor-2 (VEGFR-2), platelet-derived growth factor receptor (PDGFR), FMS-like tyrosine kinase 3 (FLT-3), and c-KIT. A phase III trial compared sorafenib and placebo after failure of prior systemic immunotherapy or in patients unfit for immunotherapy. The trial reported a 3-month improvement in progression-free survival in favor of sorafenib (22). Survival appears to improve in patients crossed over from placebo to sorafenib treatment (23).

7.3.1.2 Sunitinib

Sunitinib is an oxindol tyrosine kinase (TK) inhibitor. It selectively inhibits PDGFR, VEGFR, c-KIT, and FLT-3 and has antitumour and anti-angiogenic activity. Phase II trials with sunitinib as second-line monotherapy in patients with mRCC demonstrated a partial response in 34-40% of patients and stable disease > 3 months in 27-29% of patients (24).

In a pivotal phase III trial of first-line monotherapy comparing treatment with sunitinib versus IFN-α, sunitinib achieved a longer progression-free survival than IFN-α (11 versus 5 months; P = 0.000001). The results suggested that monotherapy with IFN-α was inferior to sunitinib in low-risk and intermediate-risk patients with mRCC (25). The overall survival was 26.4 and 21.8 months in the sunitinib and IFN-α arms, respectively (P = 0.05) (25). In patients crossed over from IFN-α to sunitinib (n = 25), median survival times were 26.4 versus 20.0 months for sunitinib and IFN-α, respectively (P = 0.03). In patients who did not receive any post-study treatment, the median overall survival reached 28.1 months in the sunitinib group versus 14.1 months in the IFN-α group (P = 0.003).

In a recent randomised phase II trial including 292 patients, sunitinib 50 mg/day (4 weeks on / 2 weeks off) was compared with a continuous uninterrupted dosage of sunitinib 37.5 mg/day in patients with metastatic clear cell renal carcinoma (26). The median time to progression with sunitinib 50 mg (4/2) (n = 146) was 9.9 months, compared with 7.1 months with 37.5 mg/day continuous dosing (n = 146). The overall response rate was 32% for 50 mg (4/2) versus 28% for 37.5 mg continuous dosing. No significant differences were observed with regard to overall survival (23.1 vs. 23.5 months; P = 0.615), commonly reported adverse events, or patient-reported kidney cancer symptoms. Because of the statistically nonsignificant but numerically longer time to progression with the standard 50 mg (4/2) dosage, the authors recommended adherence to this regimen.
7.3.1.3 Pazopanib
Pazopanib is an oral angiogenesis inhibitor that targets VEGFR, PDGFR, and c-KIT. In a prospective randomized trial of pazopanib versus placebo in treatment-naive mRCC patients and cytokine-treated patients, there was a significant improvement in the progression-free survival and tumour response (9.2 vs 4.2 months) (27). The trial showed significant results that established pazopanib as a first-line option. Since the initial phase III study involved a substantially smaller number of patients than in phase III studies of other targeted agents, the recommendation was to use pazopanib as second option in first-line treatment. Recently, the results of a randomized phase III non-inferiority trial comparing pazopanib with sunitinib (COMPARZ) showed no significant differences in the outcome parameters, with different toxicity profiles for the two drugs. With a very short follow-up period, these data are not yet mature, particularly with regard to remission. One major shortcoming of the COMPARZ trial is the fact that the study recruited almost one-third of its patients in Asia. Given the fact that there are ethnic differences in side effect profiles, the overall assessment of this trial remains unstable and further interpretation of any subgroups is almost impossible. Full publication is expected, but COMPARZ has established pazopanib as a first-line treatment option.

7.3.1.4 Axitinib
Axitinib is an oral selective second-generation inhibitor of VEGFR-1, -2, and -3 that blocks VEGFR receptors at subnanomolar drug concentrations with minimal inhibition of other targets. It has a short half-life. In the AXIS trial (a randomized phase III trial of axitinib versus sorafenib in patients in whom previous cytokine treatment or targeted agents had failed), the sample size calculation was based on a 40% improvement in the median progression-free survival PFS from 5 months to 7 months in patients randomly assigned to receive axitinib (28). Sorafenib was chosen as the comparator because at the time the trial was designed there was no standard for second-line treatment after failure of a previous VEGF targeted therapy. With 723 patients included, the overall median progression-free survival was 6.7 months for patients in the axitinib group in comparison with 4.7 months for those in the sorafenib group (hazard ratio [HR] 0.67; 95% CI, 0.54 to 0.81). However, the difference in PFS was greatest in the patients in whom cytokine treatment had failed. For those in whom sunitinib had failed (n = 194 axitinib and n = 195 sorafenib), axitinib led to a PFS of 4.8 months (95% CI, 4.5 to 6.4) versus 3.4 months (95% CI, 2.6 to 4.7) for sorafenib.

In the AXIS trial, axitinib showed greater than or equal to grade 3 toxicity for diarrhea in 11%, hypertension in 16%, and fatigue in 11%. Across all grades, nausea was recorded in 32%, vomiting in 24%, and asthenia in 21%. Overall survival (OS) was a secondary end point of the trial, but these data were not mature at the time of publication. However, since crossover was not allowed in this trial comparing two active VEGFR inhibitors, the data have in the meantime been analyzed and showed no significant differences between axitinib and sorafenib in second-line treatment (29).

7.3.1.5 Tivozanib
Tivozanib is an oral selective tyrosine kinase inhibitor targeting all three VEGF receptors. It has a long half-life. Tivozanib showed activity and tolerability in a phase II discontinuation trial. The overall response rate was 24% (95% CI, 19% to 30%), and the median PFS was 11.7 months (95% CI, 8.3 to 14.3 months) in the trial population. The most common grade 3 and 4 treatment-related adverse event was hypertension (12%) (30). The results of a phase III trial of tivozanib versus sorafenib in treatment-naive mRCC patients or those having received one prior systemic treatment excluding VEGF targeted therapy or mTOR inhibitors were reported at the American Society of Clinical Oncology (ASCO) meeting in 2012, and full publication is pending. For the 70% treatment-naive patients enrolled, the median PFS was 12.7 months for tivozanib versus 9.1 months for sorafenib (HR 0.756; 95% CI, 0.580 to 0.985). For all patients, the objective response rates were 33% for tivozanib versus 23% for sorafenib. The most common adverse events (AEs) for tivozanib (all grades / ≥ grade 3) were hypertension (46%/26%), diarrhea (22%/2%), fatigue (18%/5%), and neutropenia (10%/2%) (31). Full publication of this study is pending. If approved, tivozanib might be a tyrosine kinase inhibitor with effectiveness not inferior to that of sorafenib, as apparent in the groups of patients tested.

7.3.2 Monoclonal antibody against circulating VEGF
7.3.2.1 Bevacizumab monotherapy and combined with interferon alpha
Bevacizumab is a humanized monoclonal antibody that binds isoforms of VEGF-A. Bevacizumab 10 mg/kg every 2 weeks in patients refractory to immunotherapy was associated with an increase in the overall response (10%) and in the progression-free survival in comparison with placebo (27). A double-blind phase III trial (AVOREN) (n = 649) in patients with mRCC compared bevacizumab + IFN-α with IFN-α monotherapy (7). The median overall response was 31% in the bevacizumab + IFN-α group versus 13% in the group receiving only IFN-α (P < 0.0001). The median progression-free survival increased significantly from 5.4 months with IFN-α to 10.2 months with bevacizumab + IFN-α (P < 0.0001), but only in low-risk and intermediate-risk patients. No benefit was seen in high-risk patients. In a recent update, the median OS in the AVOREN trial, which allowed
crossover after progression, was 23.3 months for bevacizumab-IFN-α versus 21.3 months for IFN-α alone (P < 0.336) (32).

A similarly designed trial (CALGB 90206), including 732 patients (33,34), of bevacizumab (10 mg/kg intravenously every 2 weeks) plus IFN (9 million units subcutaneously three times weekly) versus IFN (9 million units subcutaneously three times weekly) showed a median PFS of 8.5 months for the combination versus 5.2 months for IFN-α alone. The median OS with a crossover design was 18.3 months for the combination versus 17.4 months for IFN-α alone. Bevacizumab plus IFN-α had a higher objective response rate (ORR) in comparison with IFN (25.5%: 95% CI, 20.9% to 30.6%; vs. 13.1%: 95% CI, 9.5% to 17.3%; P < 0.0001). The overall toxicity was greater for bevacizumab plus IFN-α, with significantly more grade 3 hypertension (9% vs. 0%), anorexia (17% vs. 8%), fatigue (35% vs. 28%), and proteinuria (13% vs. 0%).

7.3.3 Mammalian target of rapamycin (mTOR) inhibitors

7.3.3.1 Temsirolimus

Temsirolimus is a specific inhibitor of mammalian target of rapamycin (mTOR) (35). Patients with high-risk mRCC were randomly assigned in a phase III trial (NCT00065468) to receive first-line treatment with temsirolimus or IFN-α monotherapy, or a combination. In the temsirolimus group, the overall survival was 10.9 months versus 7.3 months in the IFN-α group (P < 0.0069). However, the overall survival in the temsirolimus + IFN-α group was not significantly improved (9).

7.3.3.2 Everolimus

Everolimus is an oral mTOR inhibitor. A phase III study (RECORD-1) compared everolimus plus best supportive care (BSC) versus placebo plus BSC in patients in whom previous anti-VEGFR treatment had failed. The median progression-free survival was 4 months with everolimus versus 1.9 months with placebo (P < 0.001). In the RECORD-1 trial, 124 patients (46%) had received sunitinib as the only previous systemic treatment, with a PFS of 4.0 months (95% CI, 3.7 to 5.5 months). Comparison with the AXIS data is complicated by the fact that in the RECORD-1 trial, 53% of the patients with progression after previous targeted therapy had at least more than one previous treatment, often cytokines prior to tyrosine kinase inhibitors (TKIs). In addition, the PFS analysis in this trial was not specifically carried out for previous sunitinib treatment (16,36).

7.3.4 Sequencing targeted therapy

Currently, no recommendations can be given as to the best sequence of targeted therapy. The AXIS trial is the only recent randomized phase III superiority trial comparing two TKIs after failure of a prior TKI. The results and interpretation are described under 7.3.1.3 above. For the subgroup of patients treated previously with sunitinib, the difference in PFS did not reach statistical significance for axitinib versus sorafenib, and no difference in the OS was observed. Randomized phase III trials investigating the safety and efficacy of sorafenib followed by sunitinib versus sunitinib followed by sorafenib (SWITCH-I) and sequential pazopanib and sorafenib versus sorafenib and pazopanib (SWITCH-II) are ongoing.

7.3.5 Combination of targeted agents

No recommendations can be made. At present, there have been no phase III trials reporting on a combination of two targeted agents versus monotherapy with a targeted agent. A previous randomised phase II study reported unacceptable toxicity (37). The TORAVA trial showed that the toxicity of a combination of temsirolimus and bevacizumab was much greater than anticipated and that it limited treatment continuation over time in comparison with either standard treatment with sunitinib or bevacizumab and IFN-α. In addition, clinical activity was low in comparison with the benefit expected from sequential use of each targeted therapy. This combination has not been further recommended or investigated. In a nonrandomized phase II trial, the combination of everolimus with bevacizumab was found to be effective with acceptable toxicity, except for grade 3/4 proteinuria in 25% of the patients (38). A randomised phase II trial of everolimus in combination with bevacizumab and IFN-α versus IFN-α alone is ongoing.

7.3.6 Non-clear cell renal cancer

No recommendations can be made at present. No phase III trials on systemic treatment of patients with non-clear cell carcinoma have been reported. A nonrandomized phase II trial in patients with papillary renal cancer who were treated with foretinib, a dual MET/VEGFR2 inhibitor, reported activity and acceptable toxicity with high response rates in patients with germline MET mutations (39). Patients should be treated in the framework of clinical trials. If a trial is not available, a decision can be made in consultation with the patient to perform treatment in line with clear cell renal cell carcinoma.

IFN-α = interferon alpha; MSKCC = Memorial Sloan-Kettering Cancer Center; RCC = renal cell carcinoma; TKI = tyrosine kinase inhibitor.

* Doses: IFN-α 9 MU three times per week subcutaneously, bevacizumab 10 mg/kg biweekly intravenously; sunitinib 50 mg daily orally for a period of 4 weeks, followed by 2 weeks of rest (37.5 mg continuous dosing did not show significant differences); temsirolimus 25 mg weekly intravenously; pazopanib 800 mg daily orally. Axitinib 5 mg twice daily, to be increased to 7 mg twice daily, unless greater than grade 2 toxicity, blood pressure higher than 150/90 mmHg, or the patient is receiving antihypertensive medication.

† Listed in the order of data quality.
‡ Initial phase III study; involved a substantially smaller number of patients than in phase III studies of other targeted agents.
§ No standard treatment available. Patients should be treated in the framework of clinical trials. If a trial is not available, a decision can be made in consultation with the patient to perform treatment in line with clear cell renal cell carcinoma.
¶ Poor risk criteria in the NCT00065468 trial consisted of MSKCC (3) risk plus metastases in multiple organs.

7.3.7 Conclusions

| LE |
|-----------------------------|---|
| Tyrosine kinase inhibitors (TKIs) increase the progression-free survival and/or overall survival as both first-line and second-line treatments for mRCC. | 1b |
| Sorafenib has proven efficacy as a second-line treatment after failure of cytokine therapy or in patients unfit for cytokines. | 1b |
| Axitinib has proven efficacy and superiority as a second-line treatment after failure of cytokines and VEGF-targeted therapy in comparison with sorafenib. | 1b |
| Sunitinib is more effective than IFN-α in treatment-naïve low-risk and intermediate-risk tumours. | 1b |
| Sunitinib at 50 mg (4/2) or 37.5 mg continuous dosing did not show significant differences in relation to overall survival, time to progression, response rate, or safety. | 1b |
| A combination of bevacizumab and IFN-α is more effective than IFN-α in treatment-naïve low-risk and intermediate-risk tumours. | 1b |
| Pazopanib is superior to placebo in both naïve mRCC patients and post-cytokine patients. | 1b |
| Pazopanib is not inferior to sunitinib in good-risk and intermediate-risk clear cell mRCC patients. | 1b |
| Temsirolimus monotherapy in poor-risk mRCC patients is more effective than IFN-α or temsirolimus + IFN-α. | 1b |
| Everolimus prolongs the progression-free survival in patients in whom treatment with one or two TKIs has failed in second-line or later treatments. | 1b |
The role of the new drugs is still under development and combination studies are ongoing. To date, no data are available indicating whether the new agents have a curative effect. These agents appear promising for stabilizing mRCC for a prolonged period of time. However, this promise has to be balanced against their toxicity profile and the patient’s quality of life. Anti-angiogenic monotherapy and its sequences have become the standard of care in mRCC treatment.

8. FOLLOW-UP AFTER RADICAL OR PARTIAL NEPHRECTOMY OR ABLATIVE THERAPIES FOR RCC

8.1 Introduction
Surveillance after treatment for renal cell carcinoma (RCC) allows the urologist to monitor or identify:
• Postoperative complications
• Renal function
• Local recurrence after partial nephrectomy or ablative treatment
• Recurrence in the contralateral or ipsilateral (after partial nephrectomy) kidney
• Development of metastases

The method and timing of examinations have been the subject of many publications. There is no consensus on surveillance after treatment for RCC, and in fact there is no evidence that early versus later diagnosis of recurrences improves survival. However, follow-up is important in order to increase the information about RCC available, and it should be performed by the urologist, who should record the time that has elapsed up to a recurrence or the development of metastases.

Postoperative complications and renal function are readily assessed by the patient’s history, physical examination, and measurement of serum creatinine and estimated glomerular filtration rate (eGFR). Repeated long-term monitoring of eGFR is indicated if there is impaired renal function before surgery, or postoperative deterioration. Renal function (1,2) and non-cancer survival (3-5) can be optimized by carrying out nephron-sparing surgery whenever possible for T1 and T2 tumours (6) (LE: 3). Tumour-bed recurrence is rare (2.9%), but early diagnosis is useful, since the most effective treatment is cytoreductive surgery (7,8). Recurrence in the contralateral kidney is also rare (1.2%) and is related to positive margins, multifocality, and grade (9) (LE: 3).

The reason for carrying out surveillance is to identify local recurrences or metastases at an early stage. This is particularly important with ablative therapies such as cryotherapy and radiofrequency ablation (RFA). Although the local recurrence rate is higher than after conventional surgery, the patient may still be cured using repeat ablative therapy or radical nephrectomy (10) (LE: 3). In metastatic disease, more extended tumour growth can limit the opportunity for surgical resection, which is considered the standard therapy in cases of resectable and preferably solitary lesions. In addition, in clinical trials, an early diagnosis of tumour recurrence may enhance the efficacy of a systemic treatment if the tumour burden is low.

8.2 Which investigations for which patients, and when?
Intensive radiological surveillance for all patients is unnecessary. For example, the outcome after surgery for T1a low-grade tumours is almost always excellent. It is therefore reasonable to stratify the follow-up, taking into account the risk of a recurrence or metastases developing. Although there is no randomized evidence, there have been large studies examining prognostic factors with long follow-up periods, from which some conclusions can be drawn (11-13) (LE: 4):

- The sensitivity of chest radiography for small metastases is poor and ultrasound has limitations. Surveillance should therefore not be based on these imaging modalities. With low-risk tumours, the surveillance intervals should be adapted relative to radiation exposure and benefit. Magnetic resonance imaging (MRI) can be used to reduce radiation exposure.
- When the risk of relapse is intermediate or high, computed tomography (CT) of the chest and abdomen is the investigation of choice, although the significant morbidity associated with the radiation exposure involved in repeated CT scans should be taken into account (14).
- Surveillance should also include clinical evaluation of renal function and cardiovascular risk factors.
- Positron-emission tomography (PET) and PET-CT as well as bone scintigraphy are not the standard of care in RCC surveillance, due to their limited specificity and sensitivity.

Depending on the availability of effective new treatments, more strict follow-up schedules may be required, particularly as there is a higher local recurrence rate after cryotherapy and RFA. There is controversy over the optimal duration of follow-up. Some argue that follow-up with imaging is not cost-effective after 5 years; however, late metastases are more likely to be solitary and justify more aggressive therapy with curative intent. In addition, patients with tumours that develop in the contralateral kidney can be treated with nephron-sparing surgery if the tumours are detected when small. In addition, for tumours < 4 cm in size, there is no difference between partial and radical nephrectomy with regard to recurrences during the follow-up (15) (LE: 3).

Several authors - notably Kattan, Liebovich, UCLA, and Karakiewicz (16-19) - have designed scoring systems and nomograms to quantify the likelihood of patients developing tumour recurrences, metastases, and subsequent death. These systems have been compared and validated (20) (LE: 2). Using prognostic variables,
several stage-based surveillance regimens have been proposed (21,22), but these do not include ablative therapies. A postoperative nomogram is available for estimating the likelihood of freedom from recurrence at 5 years (23). Most recently, a preoperative prognostic model based on age, symptoms, and TNM staging has been published and validated (24) (LE: 3). There is therefore a need for a surveillance algorithm for monitoring patients after treatment for RCC, recognizing not only the patient risk profile, but also the efficacy of the treatment given (Table 13).

8.3 Conclusions and recommendations for surveillance following radical or partial nephrectomy or ablative therapies for RCC

**Conclusion**
The aim of surveillance is to detect either local recurrence or metastatic disease while the patient is still surgically curable.

**Recommendations**

9. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations

ACKD  acquired cystic kidney disease
AML   Angiomyolipoma
5FU   5-fluorouracil
BSC   best supportive care
CaIX  carbonic anhydrase IX
cRCC  clear cell renal carcinoma
chRCC chromophobe renal cell carcinoma
CT    computed tomography
ESKD  end-stage kidney disease
FLT-3 FMS-like tyrosine kinase 3
GR    grade of recommendation
HIF   hypoxia inducible factor
HIFU  high-intensity focused ultrasound
HU    Hounsfield unit
IFN-alpha interferon-alpha
IL-2   interleukin-2
LE    level of evidence
MESTK mixed epithelial and stromal tumour of the kidney
mRCC  metastatic renal cell carcinoma
MRI   magnetic resonance imaging
mTOR  mammalian target of rapamycin
NSS   nephron-sparing surgery
PA    predictive accuracy
pRCC  papillary renal cell carcinoma
RCC   renal cell carcinoma
PDGF  platelet-derived growth factor
PDGFR platelet-derived growth factor receptor
PET   positron emission tomography
PTEN  phosphatase and tensin homolog
REST  Renal epithelial and stromal tumours
RF    radiofrequency
RFA   radiofrequency ablation
SAE   selective arterial embolisation
TFE3 transcription factor E3
TK    tyrosine kinase
TKI   Tyrosine kinase inhibitors
TNM   Tumour Node Metastasis
US    abdominal ultrasound
VEGF  vascular endothelial growth factor
VEGFR vascular endothelial growth factor receptor
VHL   von Hippel-Lindau

11. ABBREVIATIONS USED IN THE TEXT
1. BACKGROUND

Testicular cancer represents between 1% and 1.5% of male neoplasms and 5% of urological tumours in general, with 3-10 new cases occurring per 100,000 males per year in Western society (1-3). An increase in the incidence of testicular cancer was detected during the 1970s and 1980s, particularly in Northern European countries, and there is a clear trend towards an increased testicular cancer incidence in the last 30 years in the majority of the industrialised countries in North America, Europe and Oceania, although surprising differences in incidence rates are seen between neighbouring countries (4,5). Data from the Surveillance Epidemiology and End Results (SEER) Program during the years 1973 to 1998 show a continuing increased risk among Caucasian men in the USA only for seminoma (6).

Only 1-2% of cases are bilateral at diagnosis. The histological type varies, although there is a clear predominance (90-95%) of germ cell tumours (1). Peak incidence is in the third decade of life for non-seminoma, and in the fourth decade for pure seminoma. Familial clustering has been observed, particularly among siblings (7).

Genetic changes have been described in patients with testicular cancer. A specific genetic marker (an isochromosome of the short arm of chromosome 12 – i(12p) – has been described in all histological types of germ cell tumours (7)). Intratubular germ cell neoplasia (testicular intraepithelial neoplasia, TIN) shows the same chromosomal changes, and alterations in the p53 locus have been found in 66% of cases of testicular TIN (8).

A deregulation in the pluripotent programme of foetal germ cells (identified by specific markers such as M2A, C-KIT and OCT4/NANOG) is probably responsible for the development of TIN and germ cell neoplasia. There is overlap in the development to seminoma and embryonal carcinoma as shown by genome-wide expression analysis and detection of alpha-fetoprotein (AFP) mRNA in some atypical seminoma (9,10). Continued genome-wide screening studies and gene expression analysis data suggest testis cancer specific gene mutations on chromosomes 4, 5, 6 and 12 (namely expressing SPRY4, kit-Ligand and Synaptopodin) (11-13).

Epidemiological risk factors for the development of testicular tumours are: a history of cryptorchidism or undescended testis (testicular dysgenesis syndrome), Klinefelter’s syndrome, familial history of testicular tumours among first-grade relatives (father/brothers), the presence of a contralateral tumour or TIN, and infertility (14-20). Tallness was associated with a risk of germ cell cancer, although further confirmation is needed (21,22).

Testicular tumours show excellent cure rates. The main factors contributing to this are: careful staging at the time of diagnosis; adequate early treatment based on chemotherapeutic combinations, with or without radiotherapy and surgery; and very strict follow-up and salvage therapies. In the past decades, a decrease in the mean time delay to diagnosis and treatment has been observed (23). In the treatment of testicular cancer, the choice of centre where this treatment is going to be administered is of utmost importance. Although early stages can be successfully treated in a non-reference centre, the relapse rate is higher (24). In poor prognosis non-seminomatous germ cell tumours, it has been shown that overall survival within a clinical trial depended on the number of patients treated at the participating centre (worse < 5 patients enrolled) (25). In the same context, the frequency of post-chemotherapy residual tumour resection is associated with perioperative mortality and overall survival (26,27).

1.1 Methodology

A multidisciplinary team of urologists, medical oncologists, radiotherapists and a pathologist were involved in producing this text, which is based on a structured review of the literature from January 2008 until December 2010 for both the germ cell tumour and non-germ cell sections. Also, data from meta-analyses, Cochrane evidence, and the recommendations of the European Germ Cell Cancer Collaborative Group (EGCCCG) Meeting in Amsterdam in November 2006 have been included (28-31). A validation scoping search with a focus on the available level 1 (systematic reviews and meta-analyses of randomised controlled trials [RCTs]) data was carried out in Medline and Embase on the Dialog-Datastar platform, covering a time frame of 2009 through September 2010. The searches used the controlled terminology of the respective databases. Both MesH and EMTREE were analysed for relevant terms.

References used in the text have been assessed according to their level of scientific evidence (LE) (Table 1), and guideline recommendations have been graded (GR) (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (32). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

*Modified from Sackett et al. (32).

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence – although a very important factor – has to be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (33-35).

The EAU Guidelines Office do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

1.2 Publication history

The content of these guidelines has not changed with respect to the previous version, but for assessing the currency of the references used; replacing old references by more recent publications. This resulted in the inclusion of 5 new references. No changes in the recommendations were made. The European Association of Urology (EAU) published a first guideline on Testicular Cancer in 2001 with limited updates achieved in 2002, 2004, a major update in 2005, followed by limited updates in 2008, 2009 and 2010. Review papers have been published in the society scientific journal European Urology, the latest version dating to 2011 (36). Since 2008, the Testicular Guidelines contain a separate chapter on testicular stromal tumours.

A quick reference document presenting the main findings of the Testicular Cancer guidelines is also available, following the large text updates. All texts can be viewed and downloaded for personal use at the EAU website: http://www.uroweb.org/guidelines/online-guidelines/.

1.3 Potential conflict of interest statement

The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guidelines/.
2. PATHOLOGICAL CLASSIFICATION

The recommended pathological classification (modified from the 2004 version of the World Health Organization [WHO] guidance) is shown below (37).

1. Germ cell tumours
   - Intratubular germ cell neoplasia, unclassified type (IGCNU)
   - Seminoma (including cases with syncytiotrophoblastic cells)
   - Spermatocytic seminoma (mention if there is sarcomatous component)
   - Embryonal carcinoma
   - Yolk sac tumour
   - Choriocarcinoma
   - Teratoma (mature, immature, with malignant component)
   - Tumours with more than one histological type (specify percentage of individual components).

2. Sex cord/gonadal stromal tumours
   - Leydig cell tumour
   - Malignant Leydig cell tumour
   - Sertoli cell tumour
     - lipid-rich variant
     - sclerosing
     - large cell calcifying
   - Malignant Sertoli cell tumour
   - Granulosa cell tumour
     - adult type
     - juvenile type
   - Thecoma/fibroma group of tumours
   - Other sex cord/gonadal stromal tumours
     - incompletely differentiated
     - mixed
   - Tumours containing germ cell and sex cord/gonadal stromal (gonadoblastoma).

3. Miscellaneous non-specific stromal tumours
   - Ovarian epithelial tumours
   - Tumours of the collecting ducts and rete testis
   - Tumours (benign and malignant) of non-specific stroma.

3. DIAGNOSIS

3.1 Clinical examination
Testicular cancer generally affects young men in their third or fourth decade of life. It normally appears as a painless, unilateral mass in the scrotum or the casual finding of an intrascrotal mass (38). In approximately 20% of cases, the first symptom is scrotal pain, and up to 27% of patients with testicular cancer may have local pain (1).

Occasionally, trauma to the scrotum may reveal the presence of a testicular mass. Gynaecomastia appears in 7% of cases and is more common in non-seminomatous tumours. Back and flank pain are present in about 11% of cases (1).

In about 10% of cases, a testicular tumour can mimic an orchiepididymitis, with consequent delay of the correct diagnosis (1,2). Ultrasound (US) must be performed in any doubtful case. Physical examination reveals the features of the mass and must always be carried out in conjunction with a general examination in order to find possible (supraclavicular) distant metastases, a palpable abdominal mass or gynaecomastia. A correct diagnosis must be established in all patients with an intrascrotal mass (39).

3.2 Imaging of the testis
Currently, diagnostic US serves to confirm the presence of a testicular mass and to explore the contralateral testis. Its sensitivity in detecting a testicular tumour is almost 100%, and it has an important role in determining whether a mass is intra- or extratesticular (40). Ultrasound is an inexpensive test and should be performed even
in the presence of a testicular tumour that is clinically evident (41).

Ultrasound of the testis has to be performed in young men without a palpable testicular mass who have retroperitoneal or visceral masses or elevated serum chorionic gonadotrophin (hCG) or AFP or in men consulting for fertility problems (42-44).

Ultrasound may be recommended in the follow up of patients at risk (45), when other risk factors than microlithiasis are present (e.g. size < 12 ml or atrophy, inhomogeneous parenchyma). Solely, the presence of microlithiasis is not an indication for a regular scrotal US (46).

In the absence of other risk factors (< 12 ml (atrophy), maldescent testis), testicular microlithiasis is not an indication for biopsy or further US screening (45,47).

Magnetic resonance imaging (MRI) offers higher sensitivity and specificity than US for diagnosing tumours (40,48). MRI of the scrotum offers a sensitivity of 100% and a specificity of 95-100% (49), but its high cost does not justify its use for diagnosis.

3.3 Serum tumour markers at diagnosis

Serum tumour markers are prognostic factors and contribute to diagnosis and staging (50). The following markers should be determined:

- **AFP** (produced by yolk sac cells);
- **hCG** (expression of trophoblasts);
- **LDH** (lactate dehydrogenase).

In all tumours, there is an increase in these markers in 51% of cases of testicular cancer (23,38). Alphafetoprotein increases in 50-70% of patients with non-seminomatous germ cell tumour (NSGCT), and a rise in hCG is seen in 40-60% of patients with NSGCT. About 90% of non-seminomatous tumours present with a rise in one or two of the markers. Up to 30% of seminomas can present or develop an elevated hCG level during the course of the disease (51,52).

Lactate dehydrogenase is a less specific marker, and its concentration is proportional to tumour volume. Its level may be elevated in 80% of patients with advanced testicular cancer (51). It should be noted that negative marker levels do not exclude the diagnosis of a germ cell tumour. Other markers studied include placental alkaline phosphatase (PLAP), which may be of value in monitoring patients with pure seminoma. Cytogenetic and molecular markers are available in specific centres, but at present only contribute to research studies. Measurement of serum AFP, hCG and LDH is mandatory, while that of PLAP is optional.

3.4 Inguinal exploration and orchidectomy

Every patient with a suspected testicular mass must undergo inguinal exploration with exteriorisation of the testis within its tunics. Orchidectomy with division of the spermatic cord at the internal inguinal ring must be performed if a malignant tumour is found. If the diagnosis is not clear, a testicular biopsy (an enucleation of the intraparenchymal tumour) is taken for frozen (fresh tissue) section histological examination.

In cases of disseminated disease and life-threatening metastases, it is current practice to start with up-front chemotherapy, and orchidectomy may be delayed until clinical stabilisation has occurred.

3.5 Organ-sparing surgery

Although organ-sparing surgery is not indicated in the presence of non-tumoural contralateral testis, it can be attempted in special cases with all the necessary precautions.

In synchronous bilateral testicular tumours, metachronous contralateral tumours, or in a tumour in a solitary testis with normal pre-operative testosterone levels, organ preserving surgery can be performed when the tumour volume is less than 30% of the testicular volume and surgical rules are respected. In those cases, the rate of associated TIN is high (at least up to 82%), and all patients must be treated with adjuvant radiotherapy (16-20 Gy) at some point (53).

Infertility will result after radiotherapy and the risk of long-term Leydig cell insufficiency after radiotherapy of a solitary testis is increased (54). Radiation treatment may be delayed in fertile patients who wish to father children. The option must be carefully discussed with the patient and surgery performed in a centre with experience (55,56).
3.6 Pathological examination of the testis

Mandatory pathological requirements:

- Macroscopic features: side, testis size, maximum tumour size, and macroscopic features of epididymis, spermatic cord, and tunica vaginalis.
- Sampling: a 1 cm² section for every centimetre of maximum tumour diameter, including normal macroscopic parenchyma (if present), albuginea and epididymis, with selection of suspected areas. At least one proximal and one distal section of spermatic cord plus any suspected area.
- Microscopic features and diagnosis: histological type (specify individual components and estimate amount as percentage) according to WHO 2004 (37):
  - presence or absence of peri-tumoural venous and/or lymphatic invasion;
  - presence or absence of albuginea, tunica vaginalis, rete testis, epididymis or spermatic cord invasion;
  - presence or absence of intratubular germ cell neoplasia (TIN) in non-tumour parenchyma intratubular germ cell neoplasia.
- pT category according to Tumour Node Metastasis (TNM) 2009 (57).
- Immunohistochemical studies: in seminoma and mixed germ cell tumour, AFP and hCG.

Advisable immunohistochemical markers, in cases of doubt, are:

- in seminoma: cytokeratins (CAM 5.2), PLAP, c-kit;
- in intratubular germ cell neoplasia: PLAP, c-kit;
- other advisable markers: chromogranine A (Cg A), Ki-1 (MIB-1).

3.7 Diagnosis and treatment of testicular intraepithelial neoplasia (TIN)

Contralateral biopsy has been advocated to rule out the presence of TIN (58). Although this is routine policy in some countries, the low incidence of TIN and contralateral metachronous testicular tumours (up to 9% and approximately 2.5%, respectively) (59,60), the morbidity of TIN treatment, and the fact that most of these metachronous tumours are at a low stage at presentation make it controversial to recommend a systematic contralateral biopsy in all patients (61-63). It is still difficult to reach a consensus on whether the existence of contralateral TIN must be identified in all cases. However, biopsy of the contralateral testis should be offered to high-risk patients for contralateral TIN with a testicular volume of less than 12 mL, a history of cryptorchidism, or poor spermatogenesis (Johnson Score 1-3). A contralateral biopsy is not necessary in patients older than 40 years (64-69). A double biopsy is preferred to increase sensitivity (66).

Once TIN is diagnosed, local radiotherapy (16-20 Gy in fractions of 2 Gy) is the treatment of choice in solitary tests. Because this may produce infertility, the patient must be carefully counselled before treatment commences (61,70). In addition to infertility, Leydig cell function and testosterone production may be impaired long-term following radiotherapy for TIN (55). Radiation treatment may be delayed in fertile patients who wish to father children (66). Patients have to be informed that a testicular tumour may arise in spite of a negative biopsy (71).

If TIN is diagnosed and the contralateral testis is healthy, the options for management are orchidectomy or close observation (with a risk of 50% in 5 years to develop a testicular cancer) (72).

3.8 Screening

Although there are no surveys proving the advantages of screening programmes, it has been demonstrated that stage and prognosis are directly related to early diagnosis. In the presence of clinical risk factors, self physical examination by the affected individual is advisable.

4. STAGING

4.1 Diagnostic tools

To determine the presence of metastatic or occult disease, the half-life kinetics of serum tumour markers must be assessed, the nodal pathway must be screened, and the presence of visceral metastases ruled out. Consequently, it is mandatory to assess:

- the post-orchidectomy half-life kinetics of serum tumour markers;
- the status of retroperitoneal and supraclavicular lymph nodes, and the liver;
- the presence or absence of mediastinal nodal involvement and lung metastases;
- the status of brain and bone, if any suspicious symptoms are present.
The mandatory tests are:
- serial blood sampling;
- abdominopelvic and chest computed tomography (CT).

### 4.2 Serum tumour markers: post-orchidectomy half-life kinetics

The mean serum half-life of AFP and hCG is 5-7 days and 2-3 days, respectively (51). Tumour markers have to be re-evaluated after orchidectomy to determine half-life kinetics. Marker decline in patients with clinical stage I disease should be assessed until normalisation has occurred. Markers before start of chemotherapy are important to classify the patient according to the International Germ Cell Cancer Collaborative Group (IGCCCG) risk classification. The persistence of elevated serum tumour markers after orchidectomy might indicate the presence of metastatic disease (macro- or microscopically), while the normalisation of marker levels after orchidectomy does not rule out the presence of tumour metastases. During chemotherapy, the markers should decline; persistence has an adverse prognostic value.

### 4.3 Retroperitoneal, mediastinal and supraclavicular lymph nodes and viscera

Retroperitoneal and mediastinal lymph nodes are best assessed by means of a CT. The supraclavicular nodes are best assessed by physical examination.

Abdominopelvic CT offers a sensitivity of 70-80% in determining the state of the retroperitoneal nodes. Its accuracy depends on the size of the nodes; sensitivity and the negative predictive value increase using a 3 mm threshold to define metastatic nodes in the landing zones (69). Those figures decrease slightly in stages I and II (70,73), with a rate of understaging of 25-30% (74). New generations of CT devices do not seem to improve the sensitivity.

Magnetic resonance imaging (MRI) produces similar results to CT in the detection of retroperitoneal nodal enlargement (75,76). Again, the main objections to its routine use are its high cost and limited availability. Nevertheless, MRI can be helpful when abdominopelvic CT or ultrasound are inconclusive (75), when CT is contraindicated because of allergy to contrast media, or when the physician or the patient are concerned about radiation dose. MRI is an optional test, and there are currently no indications for its systematic use in the staging of testicular cancer.

A chest CT is the most sensitive way to evaluate the thorax and mediastinal nodes. This exploration has to be recommended in all patients with testicular cancer because up to 10% of cases can present with small subpleural nodes that are not visible radiologically (77). A CT has high sensitivity but low specificity (75).

There is no evidence to support the use of the fluorodeoxyglucose-PET (FDG-PET) in the staging of testis cancer (78,79). It is recommended in the follow-up of patients with seminoma with any residual mass at least 6 weeks after chemotherapy in order to decide on watchful waiting or active treatment (80-83). Fluorodeoxyglucose-PET, however, is not recommended in the re-staging of patients with non-seminomatous tumours after chemotherapy (84,85).

Other examinations, such as brain or spinal CT, bone scan or liver ultrasound, should be performed if there is suspicion of metastases to these organs. A CT or MRI of the skull is advisable in patients with NSGCT and multiple lung metastases and poor prognosis IGCCG risk group. Table 3 shows the recommended tests at staging.

hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase; CT = computed tomography; LH = luteinising hormone; FSH = follicle-stimulating hormone.

4.4 Staging and prognostic classifications

The staging system recommended in these guidelines is the 2009 TNM of the International Union Against Cancer (UICC) (Table 4) (57). This includes:

- determination of the anatomical extent of disease;
- assessment of serum tumour markers, including nadir values of hCG, AFP and LDH after orchidectomy (S category);
- clear definition of regional nodes;
- some N-category modifications related to node size.

Stage IA patients have primary tumours limited to the testis and epididymis, with no evidence of microscopic vascular or lymphatic invasion by tumour cells on microscopy, no sign of metastases on clinical examination or imaging, and post-orchidectomy serum tumour marker levels within normal limits. Marker decline in patients with clinical stage I disease should be assessed until normalisation. Stage IB patients have a more locally invasive primary tumour, but no sign of metastatic disease. Stage IS patients have persistently elevated (and usually increasing) serum tumour marker levels after orchidectomy, which is evidence of subclinical metastatic disease (or possibly a second germ cell tumour in the remaining testis). If serum tumour marker levels are declining according to the expected half-life decay after orchidectomy, the patient is usually followed up until normalisation.

In large population-based patient series, 75-80% of seminoma patients, and about 55% of patients with NSGCT cancer have stage I disease at diagnosis (86,87). True stage IS (persistently elevated or increasing serum marker levels after orchidectomy) is found in about 5% of non-seminoma patients. If a staging retroperitoneal lymph node dissection (RPLND) was to be performed in stage IS patients, nearly all patients would be found to have pathological stage II disease (pN+) (1,7,86,88).

In 1997, the IGCCCG defined a prognostic factor-based staging system for metastatic testis tumour based on identification of some clinical independent adverse factors. This staging system has been incorporated...
into the TNM Classification and uses histology, location of the primary tumour, location, of metastases and prechemotherapy marker levels in serum as prognostic factors to categorise patients into ‘good’, ‘intermediate’ or ‘poor’ prognosis (Table 5) (89).

*Pre-chemotherapy serum tumour markers should be assessed immediately prior to the administration of chemotherapy (same day).
PFS = progression-free survival; AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase.

4.5 Prognostic risk factors

Retrospectively, for seminoma stage I, tumour size (≥ 4 cm) and invasion of the rete testis have been identified as predictors for relapse in a pooled analysis (29). However, these risk factors have not been validated in a prospective setting except that the absence of both factors indicated a low recurrence rate (6%) (90).

For non-seminoma stage I, vascular invasion of the primary tumour in blood or lymphatic vessels is the most important predictor of occult metastatic disease. The proliferation rate, as well as the percentage of embryonal carcinoma, are additional predictors that improve upon the positive and negative predictive value of vascular invasion (91,92).

The significant prognostic pathological risk factors for stage I and clinical risk factors for metastatic disease are listed in Table 6.

4.6 Impact on fertility and fertility-associated issues
Sperm abnormalities are frequently found in patients with testis tumours. Furthermore, chemotherapy and radiation treatment can also impair fertility. In patients in the reproductive age group, pre-treatment fertility assessment (testosterone, luteinising hormone [LH] and FSH levels) should be performed, and semen analysis and cryopreservation should be offered. If cryopreservation is desired, it should preferably be performed before orchidectomy, but in any case prior to chemotherapy treatment (54,93-99).

In cases of bilateral orchidectomy or low testosterone levels after treatment of TIN, life-long testosterone supplementation is necessary (100). Patients with unilateral or bilateral orchidectomy should be offered a testicular prosthesis (101). For more detailed information, the reader is referred to the EAU Male Infertility Guidelines (102).

5. GUIDELINES FOR THE DIAGNOSIS AND STAGING OF TESTICULAR CANCER

<table>
<thead>
<tr>
<th>Testicular US is a mandatory assessment</th>
<th>GR</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td></td>
</tr>
</tbody>
</table>

| Orchidectomy and pathological examination of the testis are necessary to confirm the diagnosis and to define the local extension (pT category). In a life-threatening situation due to extensive metastasis, chemotherapy must be started before orchidectomy. | A |
| Serum determination of tumour markers (AFP, hCG, and LDH) must be performed both before and 5-7 days after orchidectomy for staging and prognostic reasons | A |
| The state of the retroperitoneal, mediastinal and supraclavicular nodes and viscera must be assessed in testicular cancer. | A |

AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase.

6. TREATMENT: STAGE I GERM CELL TUMOURS

6.1 Stage I seminoma
After modern staging procedures, about 15-20% of stage I seminoma patients have subclinical metastatic disease, usually in the retroperitoneum, and will relapse after orchidectomy alone.

6.1.1 Surveillance
Several prospective non-randomised surveillance studies have been conducted during the past decade, the largest study from Canada with > 1,500 patients (103). Previous analysis from four studies showed an actuarial 5 years’ relapse-free rate of 82.3%. The Princess Margaret Hospital series (n = 1559) showed an overall relapse rate in unselected patients of 16.8%. The actuarial relapse rate is in the order of 15-20% at 5 years, and most of the relapses are first detected in infra-diaphragmatic lymph nodes (104).
In patients with low risk (tumour size ≤ 4 cm and no rete testis invasion) the recurrence under surveillance is as low as 6% (105).

Chemotherapy, according to the IGCCCG classification, is a possible treatment for seminoma relapse under surveillance. However, 70% of patients with relapse are suitable for treatment with radiotherapy alone because of small volume disease at the time of recurrence. Patients who relapse again can be effectively treated with chemotherapy (106).

The overall cancer-specific survival rate reported under surveillance performed by experienced centres is 97-100% for seminoma stage I (104,106). The main drawback of surveillance is the need for more intensive follow-up, especially with repeated imaging examinations of the retroperitoneal lymph nodes, for at least 5 years after orchidectomy. This compares with the very low risk of subdiaphragmatic relapse after adjuvant radiotherapy.

There is a small but clinically significant risk of relapse more than 5 years after orchidectomy for stage I seminoma, which supports the need for long term surveillance.

6.1.2 Adjuvant chemotherapy
A joint trial by the Medical Research Council (MRC) and the European Organisation for Research and Treatment of Cancer (EORTC) (MRC TE 19 trial), which compared one cycle of carboplatin (area under curve [AUC] 7) with adjuvant radiotherapy, did not show a significant difference with regard to recurrence rate, time to recurrence and survival after a median follow-up of 4 years (107-109). Therefore, adjuvant carboplatin therapy using a dosage of one course AUC 7 is an alternative to radiotherapy or surveillance in stage I seminoma (104,107-109). Two courses of adjuvant carboplatin seem to further reduce the relapse rate to the order of 1-3% (110,111), but further experience and long-term observation are needed.

6.1.3 Adjuvant radiotherapy
Seminoma cells are extremely radiosensitive. Adjuvant radiotherapy to a para-aortic (PA) field or to a hockeystick field (para-aortic and ipsilateral iliac nodes), with moderate doses (total 20-24 Gy), will reduce the relapse rate to 1-3% (112-115). After modern radiotherapy, nearly all relapses will first occur outside the irradiated field (supradiaphragmatic lymph nodes or in the lungs) (112-115). Based on the results of a large randomised MRC trial, Fossa et al. (112,113) recommended radiotherapy to a PA field as standard treatment for patients with testicular seminoma stage I, T1-T3 and with undisturbed lymphatic drainage. Acute toxicity was reduced and the sperm count within the first 18 months was significantly higher after PA irradiation than after irradiation of the traditional dog-leg field. On the other hand, the relapse rate in the iliac lymph nodes was about 2% (all of them on the right side) after PA and 0% after dog-leg irradiation. Another possible site of failure is in the left renal hilum. PA irradiation should be tailored according to the site of the primary tumour. Adjuvant irradiation of supradiaphragmatic lymph nodes is not indicated in seminoma stage I.

With regard to the irradiation dose, the MRC recently finished a large randomised trial of 20 Gy versus 30 Gy PA radiation in stage I seminoma that showed equivalence for both doses in terms of recurrence rates (113). The rate of severe radiation-induced long-term toxicity is less than 2%. Moderate chronic gastrointestinal (GI) side-effects are seen in about 5% of patients, and moderate acute GI toxicity in about 60% (112). The main concern surrounding adjuvant radiotherapy is the increased risk of radiation-induced second non-germ cell malignancies (116-120).

A scrotal shield can be of benefit during adjuvant radiotherapy in order to prevent scattered radiation toxicity in the contralateral testis (119).

6.1.4 Retroperitoneal lymph node dissection (RPLND)
In a prospective, non-randomised study comparing radiotherapy and RPLND in stage I seminoma, there was a trend towards a higher incidence of retroperitoneal relapses (9.5%) after RPLND as primary treatment. Therefore, this policy should not be recommended in stage I seminoma (121).

6.1.5 Risk-adapted treatment
Using tumour size > 4 cm and rete testis invasion, patients with seminoma stage I may be subdivided into a low-and high-risk group of occult metastatic disease. Patients with and without both risk factors have a risk of occult disease of 32% and 12%, respectively. These risk factors were introduced by an analysis of retrospective trials (29). A prospective trial based on these risk factors (no risk factors: surveillance; both risk factors: two courses of carboplatin AUC 7) showed the feasibility of a risk-adapted approach. Early data with limited follow-up indicate that patients without either risk factor have a 6.0% risk of relapse at 5 years. Patients
in the high risk group treated with carboplatin experienced a 1.4% relapse rate at mean follow up of 34 months (122).

However, given the fact that cure is achieved in ~100% in patients with stage I seminoma whatever therapy used (adjuvant radiotherapy, adjuvant chemotherapy, or surveillance) and that the relapse rate in large surveillance series not using risk factors is about 15-20%, indicates a risk of over-treatment.

Therefore, the therapeutic decision should be shared with an informed patient.

### 6.2 Guidelines for the treatment of seminoma stage I

| GR | Surveillance is the recommended management option (if facilities available and patient compliant) |
|----|-------------------------------------------------------------------------------------------------
|    | Carboplatin-based chemotherapy (one course at AUC 7) is recommended.                             |
|    | Adjuvant treatment is not recommended for patients at very low risk.                            |
|    | Radiotherapy is not recommended as adjuvant treatment.                                         |

*Upgraded following panel consensus.

### 6.3 NSGCT stage I

Up to 30% of NSGCT patients with clinical stage I (CS1) disease have subclinical metastases and will relapse if surveillance alone is applied after orchidectomy.

#### 6.3.1 Surveillance

Improvements in clinical staging and follow-up methods, and the availability of effective salvage treatment with cisplatin-based chemotherapy and post-chemotherapy surgery, have led to studies of only close surveillance after orchidectomy in CS1 NSGCT patients. The largest reports of the surveillance strategy indicate a cumulative relapse rate of about 30%, with 80% of relapses occurring during the first 12 months of follow-up, 12% during the second year and 6% during the third year, decreasing to 1% during the fourth and fifth years, and occasionally even later (123-127). About 35% of relapsing patients have normal levels of serum tumour markers at relapse. About 60% of relapses are in the retroperitoneum. Despite very close follow-up, 11% of relapsing patients presented with large-volume recurrent disease.

The somewhat lower relapse rates reported from surveillance studies compared with some series of patients staged by RPLND (128) can be explained by the fact that some patients (presumably at risk) are excluded once surveillance is advised. Based on the overall cancer-specific survival data, surveillance within an experienced surveillance programme may be offered to patients with non-risk stratified clinical stage I non-seminoma as long as they are compliant and informed about the expected recurrence rate as well as the salvage treatment (129,130).

#### 6.3.2 Primary chemotherapy

Several studies involving two courses of chemotherapy with cisplatin, etoposide and bleomycin (PEB) as primary treatment for high-risk patients (having about 50% risk of relapse) have been reported (131-136). In these series, involving more than 200 patients, some with a median follow-up of nearly 8 years (131), a relapse rate of only 2.7% was reported, with very little long-term toxicity. Two cycles of cisplatin-based adjuvant chemotherapy do not seem to adversely affect fertility or sexual activity (137). However, the very-long term (> 20 years) side effects of adjuvant chemotherapy in this setting are currently unknown, and this should be taken in consideration for decision-making; especially the long-term cardio-vascular effects of chemotherapy in GCT survivors (138).

It is important to be aware of slow-growing retroperitoneal teratomas after primary chemotherapy (139).

The results of cost analyses comparing surveillance, RPLND and primary chemotherapy show different results among the reported studies, possibly because of differences in intensity and costs related to follow-up procedures (140). With a low frequency of follow-up CTs (a surveillance strategy which has been proven to be effective in non-seminoma CS1), the costs of follow-up can be considerably reduced (141).

#### 6.3.3 Risk-adapted treatment

Risk-adapted treatment is based on the risk factor vascular invasion. Stratifying patients with CS1 NSGCT
according to their presumed risk of relapse is a rational option, as several studies have reported similar survival rates and a final cure rate close to 100% with all available treatment options using the risk-stratifying approach (131-136,142-145). Risk-adapted treatment is therefore an equally effective alternative treatment of choice in CS1 NSGCT.

If the risk-adapted policy is applied, patients with vascular invasion are recommended to undergo adjuvant chemotherapy with two cycles of PEB, and patients without vascular invasion are recommended to undergo surveillance. Only if patients or doctors are not willing to accept the consequent risk-adapted treatment, or if there are circumstances that militate against the risk-adapted treatment option, should the remaining treatments be considered.

Thus, the decision about treatment should be based on a thorough discussion with the patient, taking into account the described advantages and disadvantages, as well as the individual situation of the patient and/or the treatment centre. The Swedish-Norwegian Testicular Cancer Project (SWENOTECA) recently showed that in a large population-based study with a risk-adapted approach within a management programme and a median follow-up of 4.7 years, the relapse rate was 3.2% for patients with vascular invasion treated with only one adjuvant PEB (146). Taken together, about 300 patients with high risk CS I have been adjuvantly treated with 1 x PEB with a follow-up of more than 5 yrs. As long as 1 x PEB has not been proven superior or at least equivalent to 2 courses PEB, this adjuvant treatment cannot be recommended outside of a clinical trial or a prospective registry.

6.3.4 **Retroperitoneal lymph node dissection**

If RPLND is performed, about 30% of patients are found to have retroperitoneal lymph node metastases, which corresponds to pathological stage II (PS2) disease (147-149). If no retroperitoneal metastases are found at RPLND (PS1), approximately 10% of the PS1 patients relapse at distant sites (92,129,150-152).

The main predictor of relapse in CS1 NSGCT managed by surveillance, for having PS2 disease and for relapse in PS1 after RPLND, is histopathological evidence of vascular invasion by tumour cells in, or near, the primary tumour in the testis (92,124,129,152,153). The presence of vascular invasion seems to be a very robust parameter, and is clinically usable even without centralised review by an expert panel (143,152). Vascular invasion was the most predictive of stage in a multifactorial analysis. The absence of vascular invasion has a negative predictive value of 77%, thus allowing for surveillance in low-risk compliant patients (92).

Patients without vascular invasion constitute about 50-70% of the CS1 population, and these patients have only a 15-20% risk of relapse on surveillance, compared with a 50% relapse rate in patients with vascular invasion. The risk of relapse for PS1 patients is less than 10% for those without vascular invasion and about 30% for those with vascular invasion (143,152,154,155).

If CS1 patients with PS2 are followed up only after RPLND, about 30% relapse, mainly at sites outside the abdomen and pelvis. The risk of relapse depends upon the amount of retroperitoneal disease resected (156-158). If two (or more) courses of cisplatin-based chemotherapy are given adjuvant to RPLND in PS2 cases, the relapse rate is reduced to less than 2%, including teratoma relapse (129,153,159). The risk of retroperitoneal relapse after a properly performed nerve-sparing RPLND is very low (less than 2%), as is the risk of ejaculatory disturbance or other significant side-effects (153,156,157).

The follow-up after RPLND is much simpler and less costly than that carried out during post-orchidectomy surveillance because of the reduced need for abdominal CT scans (153). If there is a rare indication to perform a staging RPLND, a laparoscopic or robot-assisted RPLND is feasible in expert hands. This minimal-invasive approach cannot be recommended as standard approach outside of a specialised laparoscopic centre (160-163). In a randomised comparison of RPLND with one course of PEB chemotherapy, adjuvant chemotherapy significantly increased the 2-year recurrence-free survival to 99.41% (confidence interval [CI] 95.87%, 99.92%) as opposed to surgery, which had a 2-year recurrence-free survival of 92.37% (CI 87.21%, 95.50%). The difference was 7.04%, CI 2.52%, 11.56%. The hazard ratio to experience a tumour recurrence with surgery as opposed to chemotherapy was 7.937, CI 1.808, 34.48. Therefore, one course of adjuvant PEB is superior to RPLND with regard to recurrence rates in patients unstratified for risk factors (164). In the SWENOTECA data mentioned in section 7.3.3 it was also found that one adjuvant PEB reduced the number of recurrences to 3.2% of the high risk and to 1.4% of the low risk patients (146).

6.4 **CS1S with (persistently) elevated serum tumour markers**

Serum tumour markers should be followed closely until levels fall into the reference values according to the expected half-life values for AFP and hCG. If the marker level increases after orchidectomy, the patient has
residual disease. If RPLND is performed, up to 87% of these patients have pathologically documented nodes in the retroperitoneum (165). An US examination of the contralateral testicle must be performed, if this was not done initially.

The treatment of true CS1S patients is still controversial. They may be treated with three courses of primary PEB chemotherapy and with follow-up as for CS1B patients (high risk, see below) after primary chemotherapy (166), or by RPLND (141). The presence of vascular invasion may strengthen the indication for primary chemotherapy as most CS1S with vascular invasion will need chemotherapy sooner or later anyway.

Treatment according to the IGCCCG classification (3-4 cycles PEB [or VIP] followed by resection in case of residual tumour)

**PEB = cisplatin, etoposide, bleomycin; CS = clinical stage; IGCCCG = International Germ Cell Cancer Collaborative Group; RPLND = retroperitoneal lymph node dissection; VIP = etoposide, cisplatin, ifosfamide.**
7. TREATMENT: METASTATIC GERM CELL TUMOURS

The treatment of metastatic germ cell tumours depends on:
- the histology of the primary tumour;
- prognostic groups as defined by the IGCCCG based on 5,202 non-seminoma and 660 seminoma cases (Table 5) (167).

7.1 Low-volume metastatic disease (stage IIA/B)

7.1.1 Stage IIA/B seminoma

So far, the standard treatment for stage IIA/B seminoma has been radiotherapy. The radiation dose delivered in stage IIA and IIB is approximately 30 Gy and 36 Gy, respectively. The standard radiation field compared with stage I will be extended from the PA region to the ipsilateral iliac field (the hockey-stick field). In stage IIB, the lateral borders should include the metastatic lymph nodes with a safety margin of 1.0-1.5 cm. This technique yields a relapse-free survival in stage IIA and IIB of 92% and 90%, respectively. Overall survival is almost 100% (168,169). Conversely, dose reduction to 27 Gy has been associated with 11% of relapses (106).

In stage IIB chemotherapy (4 x etoposide and cisplatin [EP] or 3 x PEB in good prognosis) is an alternative to radiotherapy. Although more toxic in the short term, 4 x EP or 3 x PEB achieve a similar level of disease control (170). Single-agent carboplatin is not an alternative to standard EP or PEB chemotherapy (171).

7.1.2 Stage IIA/B non-seminoma

There is a general consensus that treatment should start with initial chemotherapy in all advanced cases of NSGCT except for stage II NSGCT disease without elevated tumour markers, which alternatively can be managed by primary RPLND or surveillance to clarify stage (172,173).

If surveillance is chosen, one follow-up after 6 weeks is indicated to document whether the lesion is growing, remaining stable or shrinking. A shrinking lesion is likely to be of non-malignant origin and should be observed further. A stable or growing lesion indicates either teratoma or an undifferentiated malignant tumour. If the lesion is growing without a corresponding increase in the tumour markers AFP or beta-hCG, RPLND should be performed by an experienced surgeon because of suspected teratoma. Patients with a growing lesion and a concomitant increase in the tumour markers AFP or beta-hCG should not undergo surgery; they require chemotherapy with PEB according to the treatment algorithm for patients with metastatic disease and IGCCCG recommendations (174-176) (Figure 2). An alternative to the surveillance strategy in marker-negative II A/B non-seminoma with suspicion of an undifferentiated malignant tumour is a (computer tomography-guided) biopsy, if technically possible. There is insufficient published data on PET scans in this situation.

Patients not willing to undergo primary chemotherapy have the option of primary nerve-sparing RPLND with adjuvant chemotherapy (two cycles of PEB) in case of metastatic disease (pII A/B). Primary chemotherapy and primary RPLND are comparable options in terms of outcome but side-effects and toxicity are different, allowing for involvement of the patient in selecting the treatment of choice (177). The cure rate with either approach will be close to 98% (159,178-183).
7.2 Advanced metastatic disease

7.2.1 Primary chemotherapy

The primary treatment of choice for advanced disease is three or four cycles of PEB combination chemotherapy (Table 8), depending on the IGCCCG risk classification (see Table 3). This regimen has proven superiority to cisplatin, vinblastine and bleomycin (PVB) in patients with advanced disease (184-186). Data support a 3-day regimen of administering combination chemotherapy to be equally effective as a 5-day regimen, but associated with increased toxicity when four cycles are used (187).

*Plus hydration.

PEB = cisplatin, etoposide, bleomycin.

For patients with a ‘good prognosis’, according to the IGCCCG Classification (167), standard treatment consists of three cycles of PEB, and only in very selected cases where bleomycin is contraindicated, four cycles of EP (167,186-190). A randomised trial from the GETUG suggested that when the PEB regimen is being used in this setting the mortality was half that of EP, although the difference did not reached statistical significance (190,191). Therapy should be given without reduction of the doses at 21-day intervals; delaying the following chemotherapy cycle is justified only in cases of fever with granulocytopenia < 1000/mm³ or thrombocytopenia < 100,000/IU. There is no indication for prophylactic application of haematopoietic growth factors such as, for example, granulocyte colony-stimulating factor (G-CSF). However, if infectious complications have occurred during chemotherapy, prophylactic administration of G-CSF is recommended for the following cycles (188,192).

The ‘intermediate prognosis’ group in the IGCCCG has been defined as patients with a 5-year survival rate of about 80%. The available data support four cycles of PEB as standard treatment (167,193).

---

**Figure 2: Treatment options in patients with non-seminoma clinical stage IIA (32)**

PEB = cisplatin, etoposide, bleomycin; NS = nerve-sparing; RPLND = retroperitoneal lymph node dissection; PS = pathological stage; PD = progressive disease; NC = no change.
For patients with a ‘poor prognosis’, standard treatment consists of four cycles of PEB. Four cycles of cisplatin, etoposide and ifosfamide (PEI) have the same effect, but are more myelotoxic (194,195). The 5-year progression-free survival is between 45% and 50%. Three randomised trials have shown no advantage in high-dose chemotherapy for the overall group of ‘poor prognosis’ patients (196-198). However, patients with a slow marker decline after the first or second cycle may represent a prognostically inferior subgroup with a potential role for dose-intensified chemotherapy after detection of inadequate marker decline (196). More aggressive chemotherapy may also be investigated in a very poor prognostic group (e.g. primary mediastinal germ cell tumours or synchronous brain metastasis).

Since a matched-pair analysis resulted in a better survival rate (199-201), poor prognosis patients should still be treated in ongoing prospective trials, investigating the value of dose intensified or high-dose chemotherapy (e.g. the international GETUG 13 trial [EU-20502, NCT00104676]). Patients meeting ‘poor-prognosis’ criteria should therefore be transferred to a reference centre because a better outcome was reported for intermediate and poor prognosis patients who had been treated within a clinical trial in a high volume centre (25). There are no general recommendations for treatment modifications for patients with a poor general condition (Karnofsky < 50%) or extended liver infiltration (> 50%). Patients with extended pulmonary infiltration are at risk for acute respiratory distress syndrome: adapting the doses of the PEB regimen in the first cycle of chemotherapy (only 3 days of EP without bleomycin) was suggested to reduce the risk of early death in this setting (202).

7.3 Restaging and further treatment

7.3.1 Restaging

Restaging is performed by imaging investigations and re-evaluation of tumour markers. At marker decline and stable or regressive tumour manifestation, chemotherapy will be completed (three or four cycles, depending on the initial stage) (167,203,204). In the case of marker decline but growing metastases, resection of the tumour is obligatory after termination of induction therapy, other than in an emergency, according to local tumour growth (205).

Only with documented marker increase after two courses of chemotherapy is an early crossover of therapy indicated. These patients are usually candidates for new drugs trials (199,206). Patients with a low-level hCG marker plateau post-treatment should be observed to see whether complete normalisation occurs. Patients with a low plateau serum AFP level after chemotherapy, surgery of residual masses should be performed, with post-surgery AFP monitoring. Salvage chemotherapy is indicated for documented marker rise only (207,208).

7.3.2 Residual tumour resection

A residual mass of seminoma should not be primarily resected, irrespective of the size, but controlled by imaging investigations and tumour markers (209-215).

FDG-PET has a high negative predictive value in patients with residual masses after treatment of seminoma but false positive results can be a problem and scans should not be performed less than 2 months after chemotherapy. In patients with residuals of > 3 cm, FDG-PET should be performed in order to gain more information on the viability of these residuals. In patients with residuals of < 3 cm, the use of FDG-PET is optional (216).

On progression, salvage therapy is indicated (chemotherapy, salvage surgery, radiotherapy) (217-221). In patients with concurrent hCG elevation, progressing seminoma after first-line chemotherapy should be treated by salvage chemotherapy (or radiotherapy if only small volume recurrence is present). Progressing patients without hCG progression should undergo histological verification (e.g. by biopsy or open surgery) before salvage chemotherapy is given.

In the case of non-seminoma and complete remission after chemotherapy (no tumour visible), residual tumour resection is not indicated (222-229). The long-term relapse rate in this patient group is 6-9%, however, one third of the late relapsing patients will not survive (229).

In the case of any visible residual mass and marker normalisation, surgical resection is indicated. In patients with lesions < 1 cm, there is still an increased risk of residual cancer or teratoma (230) although the role of surgery in this setting is debated. In persistent larger volume retroperitoneal disease, all areas of primary metastatic sites must be completely resected within 4-6 weeks of completion of chemotherapy. If technically feasible, a nerve-sparing procedure should be performed (222,229-238).
Overall, following PEB induction chemotherapy, only 10% of residual masses contain viable cancer, 50% contain mature teratoma, and 40% contain necrotic-fibrotic tissue. As yet, no imaging investigations, including PET or a prognosis model, are able to predict histological differentiation of the non-seminomatous residual tumour. Thus, residual tumour resection is mandatory in all patients with residual disease > 1 cm (223-225,237-247).

The extent of surgery should be based on the risk of relapse of an individual patient and quality of life issues (232). If possible, all the masses should be resected, because a complete resection, in the setting of viable malignant cells, is more critical than recourse to post-operative chemotherapy (248). There is growing evidence that "template" resections in selected patients yield equivalent long-term results compared to bilateral systematic resections in all patients (249,250). However, the mere resection of the residual tumour (so called "lumpectomy") should not be performed.

The histology may diverge in different organ sites (240). Resection of contralateral pulmonary lesions is not mandatory in case pathologic examination of the lesions from the first lung shows complete necrosis (251).

7.3.3 Quality of surgery
Post-chemotherapy surgery is demanding and frequently needs ad hoc vascular interventions (like vena cava or aortic prosthesis). Therefore, patients should be referred to specialised centres capable of interdisciplinary surgery (hepatic resections, vessel replacement, spinal neurosurgery, thoracic surgery). Patients treated within such centres benefit from a significant reduction in perioperative mortality from 6% to 0.8% (26,252). In addition, specialised urologic surgeons are capable to reduce the local recurrence rate from 16% to 3% (253) with a higher rate of complete resections.

7.3.4 Consolidation chemotherapy after secondary surgery
After resection of necrosis or mature/immature teratoma, no further treatment is required. In the case of incomplete resection of other germ cell tumour pathologies, two adjuvant cycles of conventionally dosed cisplatin-based chemotherapy may be given in certain subgroups (e.g. ‘poor prognosis’ patients) (248,254) (caution: cumulative doses of bleomycin). After complete resection of ‘vital’ tumour < 10% of the total volume, especially in patients with an initially good prognosis group according to IGCCCG, the relapse rate is very low and adjuvant chemotherapy is not beneficial for preventing further relapse. The prognosis will definitely deteriorate if vital malignant neoplasm is found in resection specimens after second- and third-line chemotherapy. In this latter situation, post-operative chemotherapy is not indicated and is unable to improve the prognosis (236,241).

7.4 Systemic salvage treatment for relapse or refractory disease
Cisplatin-based combination salvage chemotherapy will result in long-term remissions for about 50% of the patients who relapse after first-line chemotherapy (255). The regimens of choice are four cycles of PEI/VIP (etoposide, ifosfamide, cisplatin), four cycles of TIP (paclitaxel, ifosfamide, cisplatin) or four cycles of VeIP (vinblastine, ifosfamide, cisplatin) (Table 9).

A randomised trial showed no benefit in progression-free survival nor overall survival in patients treated with 3 cycles of VeIP plus 1 cycle of high-dose chemotherapy, compared with 4 cycles of VeIP (256). At present, it is impossible to determine whether conventionally dosed cisplatin-based combination chemotherapy is sufficient as first-salvage treatment or whether early intensification of first-salvage treatment with high-dose chemotherapy should be attempted. However, there is evidence from large retrospective analyses that there are different prognostic groups in case of relapse after first line chemotherapy (257-259). An international randomised trial of high-dose versus conventional dose chemotherapy in patients with first-line relapse is planned. It is therefore of the utmost importance that these rare patients are treated within clinical trials and at experienced centres.

xx An MRC schedule uses paclitaxel at 175mg/m² in a 3 hour infusion (260).

Conventionally dosed salvage chemotherapy may achieve long-term remissions in 15-40% of patients, depending on individual risk factors (208,261-263).

The IGCCCG-2 prognostic score comprised of 7 important factors as listed in Table 10 (seminoma vs. non-seminoma histology, primary tumour site, response to initial chemotherapy, duration of progression-free interval, AFP marker level at salvage, HCG marker level at salvage, and the presence of liver, bone, or brain metastases at salvage). Using these factors, 5 risk groups (very low risk = -1 points; low risk = 0 points; intermediate-risk = 1-2 points, high risk = 3-4 points; and very high risk > 5 points) were identified with significant differences in PFS and OS. Table 9 illustrates the 5 risk groups and the corresponding 2-year PFS and 3-year OS rates (264).

IGCCCG = International Germ Cell Cancer Collaborative Group; OS = overall survival; PFS = progression-free survival.

Salvage therapy with VeIP is probably not superior to other conventionally dosed cisplatin-based combination regimens (251,254,255). Recently, paclitaxel and gemcitabine have proved to be active in the treatment of refractory germ cell tumours; both drugs are synergistic with cisplatin (265-267).

Depending on the presence of adverse prognostic factors, the results of salvage therapy after first-line cisplatin-based treatment are unsatisfactory (208,268). Although some phase II trials indicate a 10% improvement in survival with early intensification of first-salvage treatment using high-dose chemotherapy, others fail to demonstrate such improvement (260,269-272).

High dose chemotherapy offered no advantage as first salvage treatment according to the results of the randomised IT 94 trial in good prognosis patients (256). Patients with good prognostic features should therefore be offered conventional-dose first salvage treatment. However, several phase II trials, as well as one retrospectively matched-pair analysis, have shown an improvement in survival in poor-prognosis patients with early intensification of first-salvage treatment using high-dose chemotherapy (257,262,273,274). All of these patients should, if possible, be entered into ongoing studies to define the optimal approach to salvage treatment, and should be referred to centres experienced in caring for relapse and/or refractory patients (275,276).

7.4.1 Late relapse (> 2 years after end of first-line treatment)

Late relapse is defined as any patient relapsing more than 2 years following chemotherapy for metastatic non-seminoma. If technically feasible, all non-seminoma patients with late relapse should undergo immediate radical surgery of all lesions, irrespective of the level of their tumour markers to resect completely all undifferentiated germ-cell tumour, mature teratoma or secondary non-germ cell cancer (140,277). Patients with rapidly rising HCG may present an exception for immediate surgery and may benefit from induction salvage chemotherapy before complete resection. If the lesions are not completely resectable, biopsies should be obtained for histological assessment, and salvage chemotherapy should be initiated according to the histological results. In these cases consultation of an experienced pathologist is required to avoid misinterpretation of the therapeutic morphological changes in the germ cell neoplasms (278). If the patient responds to salvage chemotherapy, secondary surgery should be conducted whenever possible. In the case of unresectable, but localised, refractory disease, radiotherapy can be considered. To avoid excess mortality, late relapses should be treated only at centres experienced in managing such patients (279).

7.5 Salvage surgery

Residual tumours after salvage chemotherapy should be resected if possible. In the case of marker progression after salvage treatment and a lack of other chemotherapeutic options, resection of residual tumours (“desperation surgery”) should be considered if complete resection of all tumour seems feasible (about 25% long-term survival may be achieved) (207,233,241,244,280-289).

7.6 Treatment of brain metastases

Brain metastases occur in the frame of a systemic relapse and rarely as an isolated relapse. The long-term survival of patients presenting with brain metastases at initial diagnosis is poor (30-40%), but even poorer is the development of a brain metastasis as a recurrent disease (the 5-year survival-rate is 2-5%) (290,291). Chemotherapy is the initial treatment in this case, and some data support the use of consolidation radiotherapy, even in the case of a total response after chemotherapy (292). Surgery can be considered in the case of a persistent solitary metastasis, depending on the systemic state, the histology of the primary tumour and the location of the metastasis.

8. FOLLOW-UP AFTER CURATIVE THERAPY

8.1 General considerations

The selection of the test to be performed in follow-up should adhere to the following principles (293):
- the interval between examination and duration of testing should be consistent with the time of maximal risk of recurrence and the natural history of the tumour;
- the tests should be directed at the most likely sites of recurrence and should have a high predictive value, both positive and negative;
- therapy should be available that will result in cure of the recurrence, significant prolongation of life or palliation of symptoms. The initiation of earlier therapy should improve the outcome compared with therapy given when the patient becomes symptomatic from the tumour recurrence;
- the increased risk of second malignancy, both in the primary site and in other tissues that may have been exposed to the same carcinogens, or in which there is epidemiological evidence of increased risk, should also guide the ordering of tests. Malignant- and non-malignant complications of therapy must also be considered. Such testing should also be performed with a frequency and duration consistent with the nature of the risk, and include only tests with high positive- and negative-predictive values.

The following considerations apply in a general manner for the selection of an appropriate schedule and testing in the follow-up of all stages of testis tumour.
- Most recurrences after curative therapy will occur in the first 2 years; surveillance should therefore be most frequent and intensive during this time.
- Late relapses can occur beyond 5 years, and therefore yearly follow-up for life may be advocated.
- After RPLND, relapse in the retroperitoneum is rare, the most likely site of recurrence being the chest.
- The value of a plain radiography chest has been recently questioned in the follow-up of patients with disseminated disease after complete remission (294,295).
- CT of the chest has a higher predictive value than plain radiography chest (295).
- The results of therapy are dependent on the bulk of disease; thus an intensive strategy to detect asymptomatic disease may be justifiable.
- After chemotherapy or radiotherapy, there is a long-term risk of the development of secondary malignancies.
• Exposure to diagnostic X-rays causes second malignancies (296). Thus, the frequency of CT scans should generally be reduced and any exposure to X-rays should be well justified in a patient cohort with a very long life-expectancy after successful treatment.
• In specialised centres, CT can be substituted by MRI. However, MRI is a protocol-dependent method and, thus, should be performed in the same institution with a standardised protocol.
• With special expertise, US may be used as a method to screen the retroperitoneum during follow-up. However, the method is very much dependent on the investigator and cannot be recommended as general method during follow-up.
• Longer follow-up in patients after radiotherapy and chemotherapy is justified to detect late toxicities (e.g. cardio-vascular, endocrine).

A number of interdisciplinary organisations have presented recommendations for follow-up of testicular cancer patients (297-299). The follow-up tables presented below (tables 12 through 15) present the minimum follow-up criteria and should therefore be considered as a GRA.

8.2 Follow-up: stage I non-seminoma

Approximately 5% of patients with CS1 NSGCT present with elevated levels of tumour markers after orchidectomy, and up to 25-30% relapse during the first 2 years (5,132,152,155,178,300-303). The follow-up schedule will differ depending on which of the three possible treatment strategies was chosen:
• surveillance;
• nerve-sparing RPLND;
• adjuvant chemotherapy.

8.2.1 Follow-up investigations during surveillance

The results of a surveillance policy depend upon a careful pre-operative staging procedure and follow-up management. In a ‘wait and see’ policy, relapses will occur in 30% of cases. Of these relapses, 80% will occur in the first 12 months after orchidectomy, and approximately 12% during the second year. The median time to relapse is 6 months (range 1-62 months), but relapses after 3-5 years, and even later, can still occur, with an annual rate of 4% (113,114). Relapse occurs mainly in the retroperitoneum: approximately 70% of patients have evident metastases in the retroperitoneum, and 10% in the mediastinum and lungs (304). Sometimes the only indication is an elevated level of tumour markers.

A randomised trial of two versus five CTs has been published by the MRC recommending the reduction of imaging during surveillance in this stage to one CT scan at 3 months after orchidectomy, and another at 12 months. The trial, with a cohort of 414 patients, was powered to exclude a 3% probability of detecting a patient during surveillance only, with a relapse presenting already-metastatic disease with ‘intermediate’ or ‘poor’ prognosis features. Relapses were detected in 15% with two CTs, and 20% with five CTs; 1.6% of these patients had ‘intermediate’ or ‘poor’ prognosis features. Only 10% of patients had high-risk features (vascular invasion). In summary, this first randomised trial yielded level 1 evidence for a minimum follow-up in patients with CS1 non-seminoma (142). The recommended follow-up schedule (Table 12) includes the minimum requirements for imaging, and adds recommendations for other surveillance tests.

CT= computed tomography.

During the initial post-treatment phase, follow-up consists of regular clinical examinations, the monitoring of serum tumour markers, and imaging investigations. The frequency and type of the examinations depend on the estimated risk of relapse, the chosen treatment strategy, and the time that has elapsed since completion of therapy, and should be modified according to these risks. However, only limited information about the optimal follow-up strategy exists, and currently recommendations can only be given for seminoma (305).
For low-risk stage I non-seminoma, two abdominopelvic CTs during the first year seem sufficient to detect relapses at an early stage (142). The significance of additional CTs remains uncertain. No studies are available that address the optimal monitoring of such patients by serum tumour markers (AFP, beta-hCG).

8.2.2  **Follow-up after nerve-sparing RPLND**
Retroperitoneal relapse after a properly performed nerve-sparing RPLND is rare. RPLND should eliminate the retroperitoneal nodes as a site of relapse and thus the need for repeated abdominal CTs. The US Testicular Cancer Intergroup study data show retroperitoneal relapse in 7/264 patients with pathological stage I disease (and 20 pulmonary relapses); four of these seven had no marker elevation (306). In the Indiana series, only one relapse in 559 cases was reported (307). If a relapse occurs, it is generally in the chest, neck or at the margins of the surgical field.

Pulmonary relapses occur in 10-12% of patients, and more than 90% of those relapses occur within 2 years of RPLND (87,308). However, the low rate of retroperitoneal relapse after RPLND can only be achieved by surgery in specialised centres, as shown by the high in-field relapse rate (7/13 relapses) in the German randomised trial of RPLND versus one course of PEB (164). The recommended minimum follow-up schedule is shown in Table 13.

CT = computed tomography.

8.2.3  **Follow-up after adjuvant chemotherapy**
Prospective reports with long-term follow-up after adjuvant chemotherapy have shown a low relapse rate of about 3% (132,133,300,301). In a randomised trial with one course of PEB versus RPLND, the relapse rate with adjuvant chemotherapy was 1% (2/174 patients, one with marker relapse, one with mature teratoma in the retroperitoneum) (164). The need for repeated and long-term assessment of the retroperitoneum is still not clear. Owing to the risk of developing a late, slow-growing teratoma in the retroperitoneum after adjuvant chemotherapy, an abdominal CT should still be performed (see Table 13).

8.3  **Follow-up: stage I seminoma**
The majority of patients with seminoma (70-80%) present with clinical stage I disease at diagnosis. In 15-20% of cases, there is nodal radiological involvement at the level of the retroperitoneum, and only 5% of patients present with distant metastasis.

The relapse rate varies between 1% and 20%, depending on the post-orchiectomy therapy chosen. Only up to 30% of seminomas present with elevation of hCG at diagnosis or in the course of the disease. Consequently, in most cases, measurement of blood markers will not be a reliable test for follow-up (309). The treatment options post-orchiectomy in stage I seminoma are retroperitoneal radiotherapy, surveillance and adjuvant chemotherapy. Due to extreme radio- and chemosensitivity, high cure rates of almost 100% are reached with each of the approaches, even in cases of relapse. The costs of the different therapies vary, as do the expected side-effects (310-312).

8.3.1  **Follow-up after radiotherapy**
Low doses of radiotherapy (20-24 Gy) limited to the retroperitoneal or the hockey-stick field achieve an overall survival rate of approximately 99% at 5-10 years (113-115,313,315). The rate of relapse is 1-2% and the most common time of presentation is within 18 months of treatment (113,116,312,315,316), although late relapses have also been described (317). The site of relapse is mainly at the supradiaphragmatic lymph nodes, mediastinum, lungs or bones. In a small proportion of cases, the tumour will relapse in the inguinal or external iliac nodes. After para-aortic field RT there is also a pelvic node relapse pattern.
The side-effects of radiotherapy include temporary impaired spermatogenesis, GI symptoms (peptic ulceration), and induction of second malignancies (312,318,319). Up to 50% of patients can develop moderate toxicity grade I-II (309). The schedule of follow-up is described in Table 14.

8.3.2 Follow-up during surveillance
The actuarial risk of relapse at 5 years ranges between 6% (low risk) and 20% (119,330-334). There is no increased risk of death. The median time to relapse ranges from 12-18 months, but up to 29% of relapses can develop later than this (103,325). The sites of relapse are the PA lymph nodes in up to 82% of cases; the pelvic lymph nodes, inguinal nodes and lungs can also be affected (103,138,326-329). Due to the high and often late rate of relapse, close and active follow-up is mandatory for at least 5 years (330) (see Table 14).

8.3.3 Follow-up after adjuvant chemotherapy
One or two courses of carboplatin-based chemotherapy is an effective alternative treatment in stage I seminoma. The relapse rate is 1.9-4.5%. In general, this treatment is well tolerated, with only mild, acute and intermediate-term toxicity (330,331). Long-term data on late relapses and survival are missing (see Table 14).

8.4 Follow-up: stage II and advanced (metastatic) disease
The more advanced the nodal stage of the disease, the higher the likelihood of recurrence (159). In general, the primary tumour bulk governs the outcome for patients with NSGCT (332). In stage II NSGCT, regardless of the treatment policy adopted, excellent survival rates of 97% are reached provided that relapse is identified as soon as possible (172,173,179).

In advanced metastatic germ cell tumours, the extent of the disease correlates with the response to therapy and with survival. The combination of cisplatin-based chemotherapy and surgery (aggressive multimodality) achieves cure rates of between 65% and 85%, depending on the initial extent of disease (333,334). Complete response rates to chemotherapy are in the order of 50-60% (333); another 20-30% of patients could be rendered disease-free with post-chemotherapy surgery (335). The main reasons for failure of therapy in advanced NSGCT are (332,336,337):
- the presence of bulky disease not responding completely to chemotherapy;
- unresectable residual teratoma after chemotherapy;
- the presence or development of chemoresistant non-germ elements, which account for 8.2% of cases.

Table 15 presents the recommended minimum follow-up schedule in advanced NSGCT and seminoma.

Brain CT§ As indicated As indicated As indicated As indicated

CT = computed tomography.

*An abdominal CT must be performed at least annually if teratoma is found in the retroperitoneum.
†If the post-chemotherapy evaluation in a seminoma patient shows any mass > 3 cm, the appropriate CT should be repeated 2 and 4 months later to ensure that the mass is continuing to regress. If available, FDG-PET/CT can be performed.
‡A chest CT is indicated if abnormality is detected on a plain radiography chest and after pulmonary resection.
§In patients with headaches, focal neurological findings, or any central nervous system symptoms.

9. TESTICULAR STROMAL TUMOURS

9.1 Background
Testicular stromal tumours are rare and account for only 2-4% of adult testicular tumours. However, only Leydig cell and Sertoli cell tumours are of clinical relevance. As no general recommendations have been published to date, the Testicular Cancer Working Group of the European Association of Urology (EAU) has decided to include these tumours in the EAU Germ Cell Tumour Guidelines. Recommendations for diagnosis and treatment are given only for Leydig and Sertoli cell tumours.

9.2 Methods
A Medline search for Leydig cell tumours (synonym: interstitial cell tumour) and Sertoli cell tumours (synonym: androblastoma) was performed. Approximately 850 papers were found. After excluding pure laboratory work without clinical data, female and paediatric tumours and animal cases, 371 papers and abstracts were reviewed. Double publications and papers with unclear histology or missing data on clinical course were excluded. The majority of the remaining 285 publications are case reports, with only a few papers reporting series of more than 10 cases, most of them published in the pathology literature. The true incidence of stromal tumours therefore remains uncertain, and the proportion of metastatic tumours can only be given approximately.

Nevertheless, the symptoms for pre-operative suspicion of testicular stromal tumours and the characteristics of tumours at high risk for metastases are sufficiently well established (LE: 2a/2b) to enable recommendations to be made regarding diagnosis and surgical approach. However, no recommendations for appropriate follow-up can be given due to the absence of follow-up data in most reported cases, and the fatal outcome of metastatic tumours, irrespective of the therapy chosen.

The individual publications have been rated according to level of evidence (see above).

The literature research for clinical data on Leydig cell tumours resulted in 193 publications dealing with more than 480 tumours in adults, including three publications (1-3) reporting larger series on a total of 90 patients. Follow-up data of more than 2 years are available for about 80 patients.

The literature research for clinical data on Sertoli cell tumours resulted in 93 publications dealing with more than 260 tumours in adults, including three publications (from the same group) (4-6) reporting on a total of 80 patients. Follow-up data of more than 2 years are available in fewer than 40 patients.

9.3 Classification
The non-germ cell tumours of the testicle include the sex cord/gonadal stromal tumours and the miscellaneous non-specific stromal tumours. The different histological subtypes of testicular tumours are defined according to the WHO classification 2004 (adapted) (7).

9.4 Leydig cell tumours
9.4.1 Epidemiology
Leydig cell tumours constitute about 1-3% of adult testicular tumours (2,8) and 3% of testicular tumours in infants and children (8). The tumour is most common in the third to sixth decade in adults, with a similar incidence observed in every decade. Another peak incidence is seen in children aged between 3 and 9 years. Only 3% of Leydig cell tumours are bilateral (2). Occasionally, they occur in patients with Klinefelter’s syndrome (8).
9.4.2 Pathology of Leydig cell tumours

Leydig cell tumours are the most common type of sex cord/gonadal stromal tumours. Histopathologically, they are well outlined and usually up to 5 cm in diameter. They are also solid, coloured yellow to tan, with haemorrhage and/or necrosis present in 30% of cases. Microscopically, the cells are polygonal, with eosinophilic cytoplasm with occasional Reinke crystals, regular nucleus, solid arrangement and capillary stroma. The cells express vimentin, inhibin, protein S-100, steroid hormones, calretinin and cytokeratin (focally) (7).

About 10% of Leydig cell tumours are malignant tumours, which present with the following parameters:

- large size (> 5 cm);
- cytological atypia;
- increased mitotic activity (> 3 per 10 high-power field [HPF]);
- increased MIB-1 expression (18.6% vs 1.2% in benign);
- necrosis;
- vascular invasion (9);
- infiltrative margins;
- extension beyond the testicular parenchyma;
- DNA aneuploidy (1,10).

9.4.3 Diagnosis

Patients either present with a painless enlarged testis or the tumour is an incidental US finding. In up to 80% of cases, hormonal disorders with high oestrogen and oestradiol levels and low testosterone, increased levels of LH and FSH are reported (11,12), while negative results are always obtained for the testicular germ cell tumour-markers AFP, hCG, LDH and PLAP. Approximately 30% of patients present with gynaecomastia (13,14). Only 3% of tumours are bilateral (2). Leydig cell tumours must be distinguished from the multinodular tumour-like and often bilaterally occurring lesions of the androgenital syndrome (15).

Diagnostic work-up must include markers, hormones (at least testosterone, LH and FSH; if not conclusive, additionally oestrogen, oestradiol, progesterone and cortisol), US of both testes, and CT of chest and abdomen. On US, it may be possible to observe well-defined, small, hypoechoic lesions with hypervascularisation, but the appearance is variable and is indistinguishable from germ cell tumours (16,17). The proportion of metastatic tumours in all published case reports is only 10%. Within three larger series with longer follow-up, 18 metastatic tumours were found in a total of 83 cases (21.7%) (1-3). Histopathological signs of malignancy have been depicted above (see 4.2) (1,10). In addition, patients of older age have a greater risk of harbouring a tumour of malignant potential.

9.4.4 Treatment

Asymptomatic testicular tumours of small volume are often misinterpreted as germ cell tumours, and inguinal orchidectomy is performed. It is highly recommended to perform an organ-sparing procedure in every small intraparenchymal lesion in order to obtain the histological diagnosis. Especially in patients with symptoms of gynaecomastia or hormonal disorders, a non germ-cell tumour should be considered and immediate orchidectomy avoided (18). In cases of germ cell tumour in either frozen (fresh tissue) section or paraffin histology, orchidectomy is recommended as long as a contralateral normal testicle is present.

In stromal tumours with histological signs of malignancy, especially in patients of older age, orchidectomy and retroperitoneal lymphadenectomy is recommended to prevent metastases (19). Without histological signs of malignancy, an individualised surveillance strategy after orchidectomy is recommended (CT follow-up may be most appropriate since specific tumour markers are not available).

Tumours that have metastasised to lymph nodes, lung, liver or bone respond poorly to chemotherapy or radiation and survival is poor (19).

9.4.5 Follow-up

Recommendations for appropriate follow-up cannot be given because of the lack of follow-up data in most reported cases and the lethal outcome of metastatic tumours, irrespective of the therapy chosen.

9.5 Sertoli cell tumour

9.5.1 Epidemiology

Sertoli cell tumours account for fewer than 1% of testicular tumours, and the mean age at diagnosis is around 45 years, with rare cases under 20 years of age (4,20). On rare occasions, these tumours may develop in patients with androgen insensitivity syndrome and Peutz-Jeghers syndrome.
9.5.2 Pathology of Sertoli cell tumours

The tumour is well circumscribed, yellow, tan or white, with an average diameter of 3.5 cm (4). Microscopically, the cells are eosinophilic to pale with vacuolated cytoplasm. The nuclei are regular with grooves and there may be inclusions. The arrangement of the cells is tubular or solid; a cord-like or retiform pattern is possible. The stroma is fine and capillary, but in some cases a sclerosing aspect predominates. The cells express vimentin, cytokeratins, inhibin (40%) and protein S-100 (30%) (4).

The rate of malignant tumours ranges between 10% and 22%, and fewer than 50 cases have been reported (21-23). Signs of a malignant Sertoli tumour are:

- large size (> 5 cm);
- pleomorphic nuclei with nucleoli;
- increased mitotic activity (> 5 per 10 HPF);
- necrosis;
- vascular invasion.

9.5.2.1 Classification

Three subtypes have been described (20):

- the classic Sertoli cell tumour (4);
- the large cell calcifying form with characteristic calcifications (5,24);
- the rare sclerosing form (6,25).

9.5.3 Diagnosis

Patients present either with an enlarged testis or the tumour is an incidental US finding (26). Most classic Sertoli tumours are unilateral and unifocal. Hormonal disorders are infrequent, although gynaecomastia is sometimes seen (4). The testicular tumour-markers AFP, hCG, LDH and PLAP are always negative.

Diagnostic work-up must include tumour markers, hormones (at least testosterone, LH and FSH; if not conclusive, additionally oestrogen, oestradiol, progesterone and cortisol), US of both testes and CT of chest and abdomen.

Sertoli cell tumours are generally hypoechoic on US, but they can be of variant appearance and therefore cannot be safely distinguished from germ cell tumours (20). Only the large cell calcifying form has a characteristic image with brightly echogenic foci due to calcification (27,28).

The large cell calcifying form is diagnosed in younger men and is associated with genetic syndromes (Carney’s complex [29] and Peutz-Jeghers syndrome [30]) or, in about 40% of cases, endocrine disorders. A total of 44% of cases are bilateral, either synchronous or metachronous, and 28% show multifocality (24).

The characteristics of metastatic tumours have been depicted above (24,25). However, among patients whose tumours have been histopathologically classified as ‘malignant’ using these or similar characteristics (i.e. 18.8% of tumours in all reported cases), only 7% showed metastatic disease during follow-up.

In the largest series with the longest follow-up, 7.5% of patients had been classified as ‘malignant’ at primary diagnosis and 11.7% showed metastatic disease long-term (4). In general, affected patients are of higher age, tumours are nearly always palpable, and show more than one sign of malignancy (4).

Up to 20% of the large cell sclerosing form are malignant. There are some hints that discrimination between an early and late onset type may define a different risk for metastatic disease (5.5% compared with 23%) (20). Metastases in the infrequent sclerosing subtype are rare.

9.5.4 Treatment

Testicular tumours of small volume, otherwise asymptomatic, are often misinterpreted as germ cell tumours and inguinal orchidectomy is performed. It is highly recommended to proceed with an organ-sparing approach in small intraparenchymal testicular lesions until final histology is available. Especially in patients with symptoms of gynaecomastia or hormonal disorders or typical imaging on ultrasound (calcifications, small circumscribed tumours), organ-sparing surgery should be considered. Secondary orchidectomy can be performed if final pathology reveals a non-stromal (e.g. germ cell) tumour. Organ-sparing surgical approaches are justified as long as the remaining testicular parenchyma is sufficient for endocrine (and in stromal tumours also exocrine) function.

In tumours with histological signs of malignancy, especially in patients of older age, orchidectomy and
retroperitoneal lymphadenectomy are recommended to prevent metastases (19). Without signs of malignancy, an individualised surveillance strategy after orchidectomy is recommended (CT may be most appropriate since specific tumour-markers are not available). Tumours metastasising to lymph nodes, lung or bone respond poorly to chemotherapy or radiation, and survival is poor.

9.5.5 **Follow-up**
Recommendations for appropriate follow-up cannot be given because of the lack of follow-up data in most reported cases and the lethal outcome of metastatic tumours, irrespective of the therapy chosen.

9.6 **Granulosa cell tumour**
This is a rare tumour, with two variants: juvenile and adult.
- The juvenile type is benign. It is the most frequent congenital testicle tumour and represents 6.6% of all prepubertal testicular neoplasms. The cystic appearance is characteristic of this tumour type (31).
- With the adult type, the average age at presentation is 44 years. The typical morphology is of a homogeneous, yellow-grey tumour, with elongated cells with grooves in microfollicular and Call-Exner body arrangements.

Malignant tumours represent around 20% of cases. They are usually > 7 cm diameter. Vascular invasion and necrosis are features suggestive of malignant biology (32).

9.7 **Thecoma/fibroma group of tumours**
These tumours are very rare and benign (7).

9.8 **Other sex cord/gonadal stromal tumours**
Sex cord/gonadal stromal tumours may be incompletely differentiated or mixed forms. There is limited experience with incompletely differentiated sex cord/gonadal stromal tumours and no cases of reported metastasis (7). In mixed tumour forms, all the histological components should be reported. However, the clinical behaviour is most likely to reflect the predominant pattern or the most aggressive component of the tumour (33).

9.9 **Tumours containing germ cell and sex cord/gonadal stromal (gonadoblastoma)**
If the arrangement of the germ cells are in a nested pattern and the rest of the tumour is composed of sex cord/gonadal stroma, the term gonadoblastoma is used. It is most frequent in gonadal dysgenesis with ambiguous genitalia. Bilateral tumours are present in 40% of cases. The prognosis correlates with the invasive growth of the germinal component (34).

In the case of a diffuse arrangement of the different components, there are some doubts about the neoplastic nature of the germinal cells and some authors consider them to be entrapped rather than neoplastic (35).

9.10 **Miscellaneous tumours of the testis**

9.10.1 **Tumours of ovarian epithelial types**
These tumours resemble the epithelial tumours of the ovary. A cystic appearance with occasional mucinous material can be observed. Microscopically, the aspect is identical to their ovarian counterparts, and their evolution is similar to that of the different epithelial ovarian subtypes. Some Brenner types can be malignant (7).

9.10.2 **Tumours of the collecting ducts and rete testis**
These tumours are very rare. Benign (adenoma) and malignant (adenocarcinoma) have been reported, with malignant tumours showing local growth with a mortality rate of 56% (18).

9.10.3 **Tumours (benign and malignant) of non-specific stroma**
These are very uncommon and have a similar criteria, prognosis and treatment as do the soft tissue sarcomas.

Conflict of interest

All members of the Testicular Cancer Guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

The European Association of Urology (EAU) Guidelines Group on Penile Cancer has prepared this guidelines document to assist medical professionals in the management of penile cancer. The guidelines aim to provide detailed, up-to-date information, based on recent developments in our understanding and management of penile squamous cell carcinoma (SCC). However, it must be emphasised that these guidelines provide an updated, but not yet standardised general approach to treatment and that they provide guidance and recommendations without legal implications.

Publication history information: The Penile Cancer Guidelines were first published in 2001 and updated in 2004 and 2009. The literature search for the 2009 update covered the period from October 2004 to December 2008. The reason to present such an early update can also be attributed to the recent publication of the 2009 Tumour Node Metastasis (TNM) classification which, for penile cancer, had remained unchanged since 1987. Additionally, this update allowed inclusion of relevant new references.

2. METHODOLOGY

A systematic literature search on penile cancer was performed by all members of the EAU Penile Cancer Working Panel which covered the period between October 2004 and December 2008. At the onset of the project, each member was assigned one or two topics in accordance with their particular expertise. Each panel member was teamed up with another panel member who acted as a reviewer of a section. The panel decided to avoid rare diseases and to restrict the guidelines to SCC only. Since new publications became available in the first 3 years, the initial literature acquisition resulted in a first draft for discussion in 2008. This document was reviewed and updated by the panel and published in the 2009 edition of the EAU guidelines book and as an ultra-short (pocket) edition at the Annual EAU Congress in Stockholm, Sweden. For this 2010 print, the results of the updated search performed by the panel for their scientific publication (1) covering the period between December 2008 and December 2009 was supplemented by a second search with a cut-off date of March 2010.

To date the physician data query on ‘Penile Cancer Treatment’ (Health Professional Version) published by the National Cancer Institute, National Institutes of Health in Bethesda, MD, USA (2), remains the only evidence-based, peer-reviewed document available. No randomised controlled trials or Cochrane reviews have been published.

References used in the text have been assessed according to their level of scientific evidence (Table 1), and guideline recommendations have been graded (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (3). The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given. As a result of the lack of randomised studies, the levels of evidence (LE) and grades of recommendation (GR) provided in the document are low.

Additionally, a quick reference guide is available. All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/online-guidelines/.

3. DEFINITION OF PENILE CANCER

Penile cancer is a relatively rare SCC. It usually originates in the epithelium of the inner prepuce and glans. It shares similar pathology and natural history with SCC of the oropharynx, female genitalia (cervix, vagina and vulva), and anus. Phimosis, poor hygiene, and smoking are the major risk factors for penile cancer. Typing has been done of the human papillomaviruses (HPVs) that are responsible for the sexual transmission of genital warts, condyloma acuminata, and SCC.

An improved understanding of the natural history of the disease, earlier diagnosis, better technology, research group collaboration, and centralisation of patients in centres of excellence has improved the cure rate for penile cancer from 50% in the 1990s to 80% in recent years.

4. EPIDEMIOLOGY

In Western countries, primary malignant penile cancer is uncommon, with an incidence of less than 1.00 per 100,000 males in Europe and the United States (1,2). However, there are significant geographical variations within Europe (Figure 1), reporting an incidence greater than 1.00 per 100,000 men (3). Incidence is also affected by race and ethnicity in North America (1), with the highest incidence of penile cancer found in white Hispanics (1.01 per 100,000), followed by Alaskan, Native/American Indians (0.77 per 100,000), Blacks (0.62 per 100,000) and white non-Hispanics (0.51 per 100,000).

In contrast, in the non-Western world, the incidence of penile cancer is much higher and can represent 10-20% of malignant diseases in men ranging from an age-adjusted incidence of 0.7-3 per 100,000 people in India to 8.3 per 100,000 men in Brazil, and even higher in Uganda, where it is the most commonly diagnosed cancer.

Important risk factors include social and cultural habits, and hygienic and religious practices (4). Penile carcinoma is rare in communities that practise circumcision in newborns or before puberty (Jews, Muslims, and the Ibos of Nigeria). Early circumcision reduces the risk of penile cancer by 3-5 times. Adult circumcision does not protect against penile cancer.
In the USA, the overall age-adjusted incidence rate decreased considerably between 1973 and 2002 from 0.84 per 100,000 in 1973-1982 to 0.69 per 100,000 in 1983-1992, and further to 0.58 per 100,000 in 1993-2002 (1). In European countries, the incidence during the 1980s and 1990s was stable or increased only slightly (2). Incidence increases with age (2); however, the disease has been reported in younger men and even in children in non-western countries (3).

5. **RISK FACTORS AND PREVENTION**

Risk factors for penile cancer were identified by the Karolinska Institute based on a Medline search of published literature from 1966 to 2000 (1). Strong risk factors (OR > 10) identified by case-control studies included (LE: 2a):

- Phimosis;
- Chronic inflammatory conditions, e.g., balanoposthitis, lichen sclerosus, and atrophicus (balanitis xerotica obliterans);
- Treatment with sporalene and ultraviolet A photochemotherapy.

Sexual history (multiple partners, early age of first intercourse) and a self-reported history of condylomata are associated with a 3-5-fold increased risk of penile cancer. Smoking is also a risk factor. Cervical cancer in female sexual partners is not consistently associated with penile cancer in their male partners.

In many case series, HPV DNA has been identified in 70-100% of intraepithelial neoplasia and in 40-50% of cases with invasive penile cancer. These results have been confirmed by a population-based case-control study (2). Among men not circumcised in childhood, phimosis was strongly associated with the development of invasive penile cancer (OR: 11.4; 95% CI: 5.0-25.9) and cigarette smoking was associated with a 4.5-fold increased risk (95% CI: 2.0-10.1). Human papillomavirus DNA was detected in 80% of tumour specimens and 69% were positive for HPV-16 (LE: 2a).

Smegma as a carcinogen has been clearly excluded (3). The risk of cancer of the vulva, vagina, penis, and anus is increased in patients with condylomata acuminata (4) (LE: 2b).

Human papillomavirus-16 and 18 have a causal role in 70% of cancers of the cervix, vagina, and anus and 40-50% of cancers of the vulva, penis, and oropharynx. Other cofactors are very likely to be necessary for progression from HPV infection to cancer (5). Verrucous carcinoma is not related to HPV infection (6).

In June 2006, the US Food and Drug Administration (FDA) licensed the first vaccine to prevent cervical cancer and other HPV-associated diseases in women (7). The vaccine protects against infection with HPV-6, 11, 16 and 18, which together are responsible for 70% of cervical cancers and 90% of genital warts.

Human papillomavirus is highly transmissible, with a peak incidence soon after the onset of sexual activity. The recommended age for vaccination in girls is 11-12 years (8), with catch-up vaccination recommended in females aged 13-26 years.

However, vaccination is not a substitute for routine cervical cancer screening and vaccinated women should continue to have cervical cancer screening. Vaccination against HPV has also been recommended in men (9). Although one study has found that mid-adult women (≥ 25 years) have a high level of acceptance of HPV vaccination (10), only 33% of men wanted the HPV vaccine, 27% did not, and 40% were undecided (11). It has been decided that vaccination in men must wait for results of female HPV vaccination (12).

Interestingly, the presence of high-risk HPV DNA in penile cancer does not compromise prognosis. An early study has found no difference between HPV DNA-negative and -positive patients for lymph node metastases and 10-year survival rate (13). In a more recent study (14), disease-specific 5-year survival in the high-risk HPV-negative group was 78% versus 93% in the high-risk HPV-positive group (log rank test P = 0.03). This suggests the presence of high-risk HPV confers a survival advantage in patients with penile cancer. The virus plays an important role in oncogenesis through interaction with oncogenes and tumour suppressor genes (P53 and Rb genes) (15).

### 6. TNM CLASSIFICATION AND PATHOLOGY

#### 6.1 TNM classification

The new 2009 TNM classification for penile cancer (1) includes a change for the T1 category (Table 3). This classification needs a further update for the definition of the T2 category*. Two recent publications have shown that the prognosis for corpus spongiosum invasion is much better than for corpora cavernosa invasion (2,3).

Rees et al. (2) have investigated 72 patients with T2 tumours. Local recurrence (35% vs. 17%) and mortality (30% vs. 21%) rates were higher in patients with tunica or cavernosal involvement versus glands-only invasion after a mean follow-up of 3 years (LE: 2b). The authors have proposed defining T2a patients by spongiosum-only invasion and T2b patients by involvement of tunica or corpus cavernosum.

A retrospective analysis of the records of 513 patients treated between 1956 and 2006 has confirmed the above-mentioned difference between tumour invasion of the corpus spongiosum only versus corpus cavernosum (3). It also has confirmed that there are no differences in long-term survival between patients with T2 and T3 tumours, and no significant differences between N1 and N2 tumours in the 1987-2002 TNM classification (LE: 2a).

In the new UICC 2009 TNM classification (1), retroperitoneal node metastases are correctly and accurately defined as extraregional nodal and distant metastases. The difference between corpus spongiosum and corpora cavernosa invasion is not considered.

6.1.1 References

6.2 Pathology
Squamous cell carcinoma accounts for more than 95% of cases of malignant disease of the penis. Malignant melanoma and basal cell carcinoma are much less common. It is not known how often SCC is preceded by premalignant lesions (1-4). Although SCC is the most common penile neoplasia, different types and varying growth patterns have been identified (5-7) (Tables 4 and 5).

Differentiation grading systems for SCC
- Broders’ grading system (8)
- Maiche’s system score (9)

6.2.1 **Penile biopsy**
There is no need for biopsy if:
- there is no doubt about the diagnosis and/or;
- treatment of the lymph nodes is postponed after treatment of the primary tumour and/or after histological examination of the sentinel node(s).

There is a need for histological confirmation if:
- there is doubt about the exact nature of the lesion (e.g. metastasis or melanoma) and/or;
- treatment of the lymph nodes is based on preoperative histological information (risk-adapted strategy).

In these cases an adequate biopsy is advised. When performing a biopsy, it is important to consider the findings from a study of biopsy size. Studies of biopsies with an average size of 0.1 cm found the following difficulties:
- difficulty in evaluating the extent of depth in 91% of biopsies;
- discordance between the grade at biopsy and in the final specimen in 30% of cases;
- failure to detect cancer in 3.5% of cases (1).

Thus, although a punch biopsy may be sufficient for superficial lesions, an excisional biopsy is preferred.

6.2.2 **Pathological categories**
Traditionally, SCC has been considered as superficial or invasive. However, Cubilla et al. (5) have divided penile carcinoma into four categories:
- superficial spreading;
- vertical growth;
- verrucous;
- multicentric.

Different types of growth pattern have different prognoses (10) and different ways of dissemination. The limits of partial surgical resection must therefore be set according to the growth pattern at the time of evaluation of the frozen sections (11). If the margins are studied following these criteria (including urethral and periurethral tissue), only 3-4 mm of tumour-free tissue is sufficient to consider the surgical margins to be negative (12). Basaloid SSC is a cellular subtype that is better recognised than before, and it is highly aggressive (13).

6.2.3 **Histology and metastatic risk**
Histological subtypes carry different risks of developing metastatic lymph nodes:
- Condylomatous: 18.2%;
- SCC: 56.7%;
- Sarcomatoid carcinoma: 89%.

Perineural (14) and lymphovascular invasion (14,15) are correlated with lymph node metastases, with 23.1% of positive lymph nodes associated with a nodular pattern, and 64.6% with an infiltrative pattern. Perineural invasion, lymphovascular invasion, and high histological grade appear to be the most important adverse pathological prognostic factors, reaching 80% mortality (15).

6.2.4 **References**
7. DIAGNOSIS AND STAGING

The primary tumour and regional lymph nodes must be staged correctly to enable the most appropriate treatment.

7.1 Primary lesion

Physical examination of a patient with penile cancer includes:
- diameter of the penile lesion or suspicious areas;
- location of lesion on the penis;
- number of lesions;
- morphology of lesion: papillary, nodular, ulcerous or flat;
- relationship of lesion to other structures, e.g. submucosa, tunica albuginea, and urethra;
- corpus spongiosum and corpus cavernosum;
- colour and boundaries of lesion;
- penis length.
Accurate histological diagnosis and staging of the primary tumour and regional nodes are necessary for making treatment decisions (1). In a small series, physical examination alone proved more reliable than imaging with ultrasound (US) to judge infiltration into the corpora cavernosa (2). Artificial erection with prostaglandin E1 (alprostadil) in combination with magnetic resonance imaging (MRI) is helpful in excluding tumour invasion into the corpora cavernosa, and deciding whether limited surgery (e.g. glansectomy) can be performed (3,4).

7.2 Regional lymph nodes

7.2.1 Lymphatic drainage of the penis

Primary lymphatic drainage of penile cancer occurs to the inguinal nodes. A recent single photon emission computed tomography (CT) study (5) has shown that all sentinel nodes were located in the superior and central inguinal zones, with most found in the medial superior zone. No lymphatic drainage was observed from the penis to the two inferior regions of the groin, and no direct drainage to the pelvic nodes was visualised. These findings confirm earlier studies (6-8).

7.2.2 Non-palpable nodes

Careful inguinal physical examination is necessary. In the absence of palpable abnormalities, inguinal US (7.5 MHz) can reveal abnormal nodes and can be used as a guide for fine-needle aspiration biopsy (FNAB) (9,10). A sentinel node biopsy (SNB) (8) was not recommended until 10 years ago because of a high rate of false-negative results (25%, range: 9-50%) (11). However, recent reports have suggested that dynamic sentinel node biopsy (DSNB) using indocyanine green (ICG) and/or Tc99m-colloid isosulphan blue improves survival compared to a ‘wait-and-see’ policy (LE: 3), and reduces side effects compared to those with inguinal lymphadenectomy (LAD) (12,13). Prospective studies on DSNB have obtained 100% specificity and 95% sensitivity (14-18) (LE: 2b). As analysis of dynamic SNB is operator-dependent (19) and relies on experience, the procedure is only available in a few centres. Nevertheless, a two-centre evaluation of DSNB has demonstrated the reproducibility of the technique, with a short learning curve (20).

Iliac lymph node metastases do not occur in the absence of inguinal metastases (19), therefore pelvic CT is not necessary in patients with no inguinal node metastases.

Conventional CT or MRI cannot detect micrometastases (21). No further studies have been performed to confirm the promising results reported with nanoparticle-enhanced MRI (22), but positron emission tomography (PET/CT) can detect pelvic and distant metastases (23).

7.2.3 Risk factors and metastasis detection

Patients with T1G1 category tumours do not need further therapy after local treatment, but in 13% up to 29% of cases those with intermediate T1G2 tumours can develop lymph node metastases (23,24). The risk for lymph node involvement can be evaluated by T and G categories and from other tumour characteristics.

Risk factors identified from retrospective studies include several pathological parameters, such as: perineural invasion, lymphovascular invasion, tumour depth or thickness, anatomical site, size and growth pattern, infiltrative front of invasion, positive resection margins, and urethral invasion (25). Several large series have identified lymphovascular invasion alone, lymphovascular invasion with absence of koilocytosis, lymphovascular invasion plus palpable inguinal nodes, and high histological grade plus perineural invasion as the most important risk factors (26-28).

Finally, the most adverse pathological prognostic factors appears to be lymphovascular invasion and high histological grade (28).

Nomograms have been used to evaluate the predictive value of clinical and pathological indicators, but pathological parameters and nomograms (23-30) cannot achieve more than 80% prediction (23-30). Only 18fluorodeoxyglucose (FDG) PET/CT can improve the detection of early regional and distant metastases (31).

7.2.4 Palpable nodes

Palpable nodes should be described as follows:

• node consistency;
• node location;
• diameter of nodes or masses;
• unilateral or bilateral location;
• number of nodes identified in each inguinal area;
• mobile or fixed nodes or masses;
• relationship (e.g. infiltration or perforation) to other structures, such as the skin or cooper ligament;
• oedema of leg and/or scrotum.

Palpable lymph node metastases can be diagnosed using percutaneous FNAB (cytology and/or histology
At the time of diagnosis of penile cancer, as many as 50% of palpable inguinal nodes will be reactive for concomitant infection rather than due to lymph node metastasis. In contrast, during follow-up, nearly 100% of enlarged nodes are metastatic (32) (LE: 2b).

Thus, after allowing time for inflammatory reactions to subside, regional nodes should be evaluated within a few weeks after treatment of the primary tumour. Histological diagnosis can be done using fine-needle aspiration, tissue core, or open biopsy, according to the preference of the pathologist (32,33) (LE: 2b). In the case of a negative biopsy and clinically suspicious nodes, a repeat or excisional biopsy should be performed.

### Conclusion

Imaging techniques (e.g. CT and MRI) are widely used, but they are only useful for staging patients with centrimetrical, or lymph node metastases ≥ 1 cm. So far, no current imaging modality can identify microscopic invasion. Imaging using 18FDG-PET/CT have some minor limitations (0.5 cm) (31). The use of molecular biological techniques is experimental (37-41).

### Distant metastases

An assessment of distant metastases should be performed in patients with positive inguinal nodes (23-35) (LE: 2b). PET/CT is reliable for identification of pelvic and distant metastases in patients with positive inguinal nodes (31). Routine blood analysis and plain radiography chest are usually performed, despite the fact that they have limited use and lung metastases are exceptionally rare. The value of SCC antigen determination as a staging tool is unclear and therefore not recommended for routine use (37). Biological studies are investigational (38-41).

A diagnostic schedule is summarised below.

8. TREATMENT

The primary tumour and regional lymph nodes are usually treated separately. Although it is important to avoid overtreatment, which can lead to loss of penile tissue and adverse effects of an unnecessary lymphadenectomy, it is essential to remove all cancerous tissue with healthy margins.

8.1 Primary tumour

Guidelines on treatment strategies for primary tumour in penile cancer are outlined in Table 6. For small lesions, a penis-preserving strategy is recommended (GR: B). There is a variety of treatment modalities, which have not been compared in a scientifically rigorous manner, and providing recommendations based on published data is therefore difficult. However, treatment choice is influenced by tumour size, its position on the glans or in the corpora cavernosa, and experience of the treating urologist. There are no documented differences in the local recurrence rate between surgery, laser therapy, and radiotherapy. Although conservative surgery improves quality of life, the risk of local recurrence is higher than after ablative surgery (27% vs. 5%). The pathological assessment of surgical margins is essential to guarantee tumour-free margins (1). Tumour-positive margins lead inevitably to local recurrence. Total removal of the glans (glansectomy) and prepuce does have the lowest recurrence rate among the treatment modalities for small penile lesions (2%) (2).

8.1.1 Categories Tis, Ta, and T1a

Superficial lesions can be treated with one of the following penis-sparing techniques: LE

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

8.1.2 Category T1b tumours of the glans with deeper infiltration (> 1 mm)

These tumours can be treated with the following techniques: LE

<table>
<thead>
<tr>
<th>Treatment</th>
<th>Level</th>
</tr>
</thead>
<tbody>
<tr>
<td>Wide local (laser) excision plus reconstructive surgery or total glans resurfacing with or without skin transplantation (8).</td>

</tr>
<tr>
<td>Radiotherapy (see section 8.1.7).</td>
<td></td>
</tr>
<tr>
<td>Glansectomy (2,8-11).</td>
<td>2b</td>
</tr>
</tbody>
</table>

Conservative treatment may be less suitable in cases of multifocal lesions, which are responsible for 15% of recurrences. Total treatment of the glans surface combined with concomitant circumcision is recommended to avoid multiple recurrences (3) (GR: C).
Negative surgical margins are imperative when using penile-conserving treatments. Pathological assessment of the surgical margins is recommended (GR: C). In general, a margin of 3 mm is considered safe (1).

8.1.3  **Category T2 (limited to the glans)**
Total glansectomy, with or without resurfacing of the corporeal heads, is recommended (8, 10) (LE: 2b; GR: B). Radiotherapy is also an option (see section 8.1.7). Partial amputation should be considered in patients who are unfit for more conservative reconstructive surgery (11) (GR: C).

8.1.4  **Local disease recurrence after conservative surgery**
A second conservative procedure is advised if there is no corpus cavernosum invasion (2-8) (GR: C). If there is a large or deep infiltrating recurrence, partial or total amputation is inevitable (11) (GR: B). For those cases a total phallic reconstruction should be considered (12, 13).

8.1.5  **Category T2 with invasion into the corpus cavernosum**
Partial amputation with a tumour-free margin is considered standard treatment (11) (GR: B). A surgical margin of 5-10 mm is considered safe (1). Reconstruction may alleviate the mutilation (10, 12, 13).

8.1.6  **Categories T3 and T4**
These categories of patients are rare (e.g., 5% in Europe and 13% in Brazil) (13). Total penectomy with perineal urethrostomy is standard surgical treatment for T3 tumours (14) (GR: B). Spatulating the urethra is helpful in preventing stenosis. In more advanced disease (T4), neoadjuvant chemotherapy is advised, followed by surgery in responding patients (as for management of patients with fixed or relapsed inguinal nodes (see section 8.2.4) (GR: B). Otherwise, adjuvant chemotherapy or consolidating radiation is advised (GR: C; see sections 8.2.4 and 8.1.7).

8.1.7  **Radiotherapy**
Radiotherapy of the primary tumour is an alternative organ-preserving approach with good results in selected patients with T1-2 lesions < 4 cm in diameter (15-18) (LE: 2b). Best results have been obtained with brachytherapy with local control rates ranging from 70-90% (15, 17). Patients with lesions > 4 cm are not candidates for brachytherapy.

A minimum dose of 60 Gy is given for external radiotherapy combined with a brachytherapy boost, or brachytherapy alone (15-18). The penile preservation rate after radiotherapy is approximately 80%. Local failure rates after radiotherapy are higher than after partial penectomy, but salvage surgery can restore local control (16). The following complications are the most prevalent: urethral stenosis (20-35%), glans necrosis (10-20%), and late fibrosis of the corpora cavernosa (18) (LE: 3).

No scientifically sound recommendations can be given regarding surgical procedures versus radiotherapy. Institutional experience and available techniques play an important role in decision making.

8.1.8  **Guidelines for treatment strategies for penile cancer**
Table 6 provides a graded treatment schedule, also including the level of the underlying evidence on which the recommendations are based.

**Category T4**
(Other adj. structures)
Eligible patients: neoadjuvant chemotherapy followed by surgery in responders.
Alternative: external radiation.

**Local disease recurrence after conservative therapy**
Salvage surgery, consisting of penis-sparing treatment in small recurrences.
Larger recurrence: some form of amputation.

**Radiotherapy**
Organ-preserving treatment in selected patients with T1-T2 of glans or coronal sulcus, lesions < 4 cm.

**Chemotherapy**
Neoadjuvant, before surgery.
Palliation in advanced or metastatic disease.

CO₂ = carbon dioxide; Nd:YAG = neodymium:yttrium-aluminum-garnet.

**8.2 Regional lymph nodes**
Guidelines on treatment strategies for nodal metastases are presented in section 8.2.7. Lymphadenectomy is the treatment of choice for patients with inguinal lymph node metastases (GR: B). The procedure requires careful skin-flap management, meticulous lymph node dissection, prophylactic antibiotics, compression stockings, and early ambulation. Prolonged lymph leakage, leg and scrotal lymphoedema, skin-flap necrosis, and wound infection can occur in 30-70% of patients (14) (LE: 2b). Recent studies have shown a decrease in complications, which suggests that these procedures should be done by experienced surgeons (19).

**8.2.1 Surveillance**
Surveillance can be recommended only in patients with Tis, Ta, and T1G1 tumours (14,19,20).

**8.2.2 Management of patients with non-palpable inguinal nodes**
All non-invasive diagnostic procedures miss approximately 20% of microscopic metastases. Also, the sensitivity of a published nomogram does not exceed 80% (21) (LE: 2b). Various risk factors have been helpful in stratifying node-negative patients for lymph node dissection (14,19-21) (LE: 2b). This approach was the basis for the 2004 guideline recommendations for the management of clinically node-negative patients (22). In centres without sentinel node diagnostics, these recommendations can still be useful. In addition, T1G2 tumours should be considered intermediate risk, based on a recent analysis (23). The experience from Brazil can be used as a gold standard for survival rates that can only be attained by surgery (14,19). Only DSNB has better sensitivity (94%) (24) (LE: 2b).

To identify the sentinel nodes reliably, preoperative mapping is essential. Tc99m nanocolloid is injected the day before surgery, patent blue is injected, and a γ-ray detection probe is used intraoperatively. Complete inguinal LAD is performed only in tumour-positive patients. The current protocol has a sensitivity of 95% (24). The technique is now reproducible with a short learning curve (25) (GR: B).

Considering the rarity of the disease and possible improvements in diagnosis and treatment, centralisation of patients is recommended. Centralisation of patients with penile SCC in 10 centres in the United Kingdom allowed improvement in the cure of the disease within a few years (26).

**8.2.3 Management of patients with palpable inguinal nodes**
US-guided FNAB provides an excellent, rapid, and easy way to detect metastatic nodal involvement (27) (LE: 3). In suspected cases with tumour-negative findings, various strategies can be followed:
(1) Antibiotics are given;
(2) FNAB is repeated;
(3) Suspected nodes are surgically removed;
(4) Inguinal LAD is performed. Dynamic sentinel node biopsy is not reliable in patients with palpable suspected nodes and should not be used (28) (LE: 3); DSNB can be used for the clinically uninvolved side and LAD is performed at the tumour-positive sites. Inguinal LAD has been shown to have significant morbidity and it is to be limited to positive sides.

In advanced cases, reconstructive surgery is often necessary for primary wound closure (29). Modified inguinal LAD is associated with less morbidity, but reducing the field of dissection increases the possibility of false-negative results. Current knowledge on lymphatic drainage of the penis suggests that modified LAD should dissect at least the central and both superior Daseler’s zones (30,31) (LE: 3).

There is no direct lymphatic drainage from penile tumours to the pelvic lymph nodes (30), therefore, pelvic LAD is not needed if there is no involvement of inguinal nodes or there is only one intranodal metastasis (14,19) (LE: 3).

In contrast, pelvic LAD is recommended if the node of Cloquet or two or more inguinal nodes are involved.
are involved. The rate of positive pelvic nodes was found to be 23% in cases with more than two positive inguinal nodes, and 56% for those with more than three positive inguinal nodes, or if there was extracapsular involvement in at least one inguinal node (14,19) (LE: 2b). Pelvic LAD can be performed as a secondary procedure.

If bilateral dissection is indicated, it can be performed though a midline suprapubic extraperitoneal incision. It is also important to avoid delay for LAD (31). Laparoscopy is not suitable for radical surgery.

8.2.4 Adjuvant chemotherapy
Adjuvant chemotherapy after resection of nodal metastases has been reported in a few small heterogeneous series. Nevertheless, at the National Cancer Institute in Milan, Italy, a long-term disease-free survival (DFS) rate of 84% was obtained in 25 consecutive node-positive patients treated with 12 adjuvant weekly courses of VBM during the period 1979-1990 (32,33). This compares with a DFS rate of only 39% for 38 consecutive patients who underwent radical LAD, with or without complementary radiotherapy, in the period 1960-1978 (32).

Since 1991, category pN2-3 patients have received three courses of adjuvant cisplatin and 5-FU, with lower toxicity and even better results compared to VBM (33) (LE: 2b). Category pN1 patients do not need adjuvant chemotherapy (33) (LE: 2b).

8.2.5 Management of patients with fixed or relapsed inguinal nodes
Upfront surgery is not recommended (GR: B) because cure is unlikely, survival is short, and the surgery is usually quite destructive. Upfront chemotherapy followed by surgery is promising, and these procedures should be performed by experienced medical oncologists and surgeons (14,32,33).

Multiple regimens have been used in a small number of patients. Cisplatin, methotrexate, and bleomycin (BMP) at Memorial Sloan-Kettering Cancer Center in New York have shown promising results, but a confirmatory study by the Southwest Oncology Group has reported unacceptable toxicity and only modest results (34).

Leijte et al. have reported on 20 patients with five different neoadjuvant chemotherapy regimens in the 1972-2005 period (36). Responders underwent post-chemotherapy surgery and achieved a 37% long-term survival rate. At the MD Anderson Cancer Center, combination therapy with paclitaxel, carboplatin or paclitaxel, cisplatin, and ifosfamide has been used in seven patients, followed by surgery (37). Four patients were long-term survivors (48-84 months) but none of the other three patients treated with BMP achieved significant remission.

A preliminary study on taxol combined with cisplatin and 5-FU has shown significant responses in five of six patients with fixed or relapsed inguinal nodes, but only the three who underwent post-chemotherapy surgery achieved durable complete remission (38).

8.2.6 The role of radiotherapy
Prophylactic radiotherapy in patients with N0 tumours is not recommended (GR: C) because of:
- failure to prevent the development of metastatic lymph nodes;
- complications of radiotherapy;
- more difficult follow-up due to fibrotic changes.

Adjuvant radiotherapy may improve locoregional control in patients with extensive metastases and/or extranodal spread, but control is achieved at the cost of severe side effects including severe oedema and pain (GR: C).

20 PENILE CANCER - UPDATE APRIL 2010
Palpable inguinal nodes

US-guided FNAB (DSNB is unsuitable for palpable nodes).

Negative biopsy: surveillance (repeat biopsy).

Positive biopsy: inguinal LAD on positive side.

(NB: Modified LAD must include the central zone and both superior Daseler’s zones).

Pelvic nodes

Pelvic LAD if there is: extranodal metastasis; Cloquet node involved; > 2 inguinal node metastases.

Unilateral pelvic LAD if unilateral lymph node metastases with prolonged inguinal incision.

Bilateral pelvic LAD if bilateral inguinal metastases.

Adjuvant chemotherapy

In patients with > 1 intranodal metastasis (pN2 pN3) after radical LAD, survival is improved by adjuvant chemotherapy (3 courses of cisplatin, fluorouracil [PF] chemotherapy).

Patients with fixed or relapsed inguinal nodes

Neo-adjuvant chemotherapy is strongly recommended in patients with unresectable or recurrent lymph node metastases.

Taxanes seems to improve the efficacy of standard PF chemotherapy (or carboplatin).

Radiotherapy

Curative radiotherapy may be used for primary tumours of the glans penis and sulcus < 4 cm or for palliation.

Prophylactic radiotherapy in clinical N0 patients is not indicated.

DSNB = dynamic sentinel node biopsy; FNAB = fine-needle aspiration biopsy; LAD = lymphadenectomy.

8.3 References

9. FOLLOW-UP

Follow-up in penile carcinoma is important for several reasons:
• It enables early detection of recurrence, which is important because most local and/or loco-regional recurrences are potentially curable.
• It is the only way to assess treatment and anticipate early and late complications.
• It is important for patient (and physician) education.

A rational follow-up scheme requires an understanding of the patterns of recurrence. Preferably, follow-up should be introduced within the framework of a controlled study. Based on a retrospective study, a follow-up schedule for penile cancer has been published (1).

9.1 How to follow-up

The aim of follow-up is to detect local and/or regional recurrences because they can be cured. In contrast, metastases at distant sites are always fatal (2). Risk stratification for recurrence is also helpful. Traditional follow-up methods are inspection and physical evaluation. Modern US is a useful adjunct, with promising results from new imaging modalities, such as PET/CT (3).

9.2 When to follow-up

The follow-up interval and strategies for patients with penile cancer are directed by the initial treatment of the primary lesion and regional lymph nodes. In the above-mentioned multicentre study (1), during the first 2 years of follow-up, the following occurred:
• 74.3% of all recurrences;
• 66.4% of local recurrences;
• 86.1% of regional recurrences;
• 100% of distant recurrences.

Of all recurrences, 92.2% occurred within the first 5 years (1). All recurrences after 5 years were
local recurrences or new primary lesions. Thus, an intensive programme of follow-up during the first 2 years is rational, with less intensive follow-up needed thereafter. In well-educated and motivated patients, follow-up can stop after 5 years, although they must continue to carry out regular self-examination.

### 9.3 Primary tumour

Local recurrence has been reported in up to 30% of patients treated with penis-preserving surgery, during the first 2 years following treatment. Local recurrence is more likely with all types of local therapy, that is, local resection, laser therapy, brachytherapy, Mohs’ procedure, and associated therapies (1,4). However, in contrast to regional recurrence, local recurrence does not have an impact on survival (1,4).

Local recurrences are easily detected by the patient, his partner or doctor. Patient education is an important part of follow-up and the patient should be urged to visit a specialist if any changes are seen. Despite the fact that late local recurrences are well documented, it is reasonable to stop follow-up after 5 years, provided the patient will report local changes immediately (5). This is possible because life-threatening regional and distant metastases no longer occur, while recurrences that are local only are not life-threatening. The emphasis should be placed on patient self-examination. In patients who are unlikely to self-examine, long-term follow-up may be necessary.

Following penis-preserving treatment, a follow-up visit every 3 months is advised in the first 2 years. We then advise a follow-up visit every 6 months, provided that the patient and his partner have been well instructed to examine the penis regularly and to return if any abnormality is observed. It is important to stress that the patient must continue to carry out regular self-examination even after 5 years’ follow-up. After amputation, a less frequent time interval of every 6 months is advised. The risk of local recurrence is no more than 5% (1,4).

### 9.4 Regional recurrences

Stringent follow-up is advised for the 2 years following surgery. This is because most regional recurrences occur within that time, whether a ‘wait-and-see’ policy has been followed or the patient has undergone SNB or inguinal LAD.

Previous follow-up recommendations have relied heavily on physical examination of the inguinal regions. However, experience with ‘wait and see’ and DSNB have shown that, despite intensive follow-up, regional recurrences have shown up unexpectedly (6). US and immediate FNAB have been encouraging in finding occult metastases (6,7), and it seems reasonable to add US to physical examination.

Patients managed with a ‘wait-and-see’ policy have a higher risk of recurrence (9%) than patients staged surgically (2.3%), irrespective whether staging has been performed by LAD or DSNB. This finding only applies to patients without histopathological evidence of lymph node metastases.

Patients treated surgically because of lymph node metastases have an increased risk of recurrence (19%) (1). Based on these findings, a change in the follow-up scheme is proposed. For patients in a ‘wait-and-see’ programme and those treated with LAD for proven lymph node metastases, follow-up should be every 3 months and should include US investigation of the groin. This intensive follow-up programme should be observed for 2 years, which is the period when recurrence is most likely. Imaging using CT has been replaced by US scanning with immediate FNAB, and PET/CT is used in patients at risk of regional recurrence and distant metastases. Bone scan and other tests are only recommended in symptomatic patients.

### 9.5 Guidelines for follow-up in penile cancer

10. QUALITY OF LIFE

10.1 Sexuality and fertility after cancer
As more people achieve long-term survival after cancer, sexual dysfunction and infertility are increasingly recognised as negative consequences that affect the quality of life (1).

10.1.1 Sexual activity and quality of life after penile cancer laser treatment
A retrospective, face-to-face, structured interview study was carried out on Swedish patients treated with laser for localised penile carcinoma during 1986 to 2000 (2). Sixty-seven patients were treated, with 58 of them (mean age 63 years) still alive in 2006. Forty-six (79%) agreed to participate in the interview. Nearly all patients could recall their first symptom, with 37% reporting that they delayed seeking treatment for > 6 months. Patients had a greater lifetime number of sexual partners and a greater lifetime prevalence of sexually transmitted infections than the comparable general Swedish population. Following laser treatment, there was a marked decrease in some sexual practices, such as manual stimulation or caressing and fellatio. Patient satisfaction with life overall was similar to that of the general population.

In conclusion, some patients delayed seeking treatment for a considerable period despite awareness of the first local symptoms. Men with laser-treated localised penile carcinoma resumed their sexual activities to a large extent. Except for satisfaction with somatic health, a similar (or higher) proportion of patients were satisfied with life overall and with other domains of life including their sex life.

10.1.2 Sexual function after partial penectomy for penile cancer
To compare sexual function and satisfaction before and after partial penectomy, 18 Brazilian patients were given a personal interview and answered the International Index of Erectile Function questionnaire to determine erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction with sexual activity (3). The median patient age was 52 years. The median penile length after partial penectomy was
4 cm in the flaccid state, with 55.6% of patients reporting erectile function that allowed sexual intercourse. The main reason given for not resuming sexual intercourse in 50% of sexually abstinent patients was feeling shame because of a small penis and the absence of the glans penis. Surgical complications also compromised resumption of sexual activity after amputation in 33.3% of these patients. However, 66.7% sustained the same frequency and level of sexual desire prior to surgery, and 72.2% continued to have ejaculation and orgasm every time they had sexual stimulation or intercourse. Nevertheless, only 33.3% maintained their preoperative frequency of sexual intercourse and were satisfied with their sexual relationships with their partners and their overall sex life. In conclusion, the preoperative and postoperative scores were statistically worse for all domains of sexual function after partial penectomy.

10.2 Sexual mutilation, relapse, and death
Today, nearly 80% of penile cancer patients can be cured. Experience in management of this rare tumour is helpful (4). Referral to centres with experience is recommended. Psychological support is very important for these patients. Penis-sparing surgery obviously allows a better quality of life than penile amputation and must be considered whenever feasible.

1. INTRODUCTION

Lower urinary tract symptoms (LUTS) in elderly men were traditionally attributed to the enlarging prostate. The mechanisms invoked were one or all of the following: histological benign prostatic hyperplasia (BPH), benign prostatic enlargement (BPE), or benign prostatic obstruction (BPO). However, during the last decade the causal link between the prostate and the pathogenesis of LUTS has come into question (1). Although the enlarged prostate can contribute to the onset of LUTS in a proportion of men over 40 years of age, other factors are of equal importance. Latest knowledge suggests that LUTS may be linked to the prostate (BPH-LUTS), bladder (detrusor overactivity-overactive bladder syndrome [OAB], detrusor underactivity) or kidney (nocturnal polyuria) (1). Because of the great prevalence of BPH in elderly men, which is as high as 40% in men in their fifth decade and 90% in men in their ninth decade (2), microscopical changes of the prostate seem to co-exist silently with other bladder or kidney malfunctions in some men. The many causes of LUTS are illustrated in Figure 1. In any single person complaining of LUTS it is common for more than one of these factors to be present. This multi-factorial view of the aetiology of LUTS has led most experts to regard the whole urinary tract as a single functional unit. This broader, more complex approach to the pathogenesis of LUTS meant that we modified the title - to reflect the change in perspective - from the former EAU Guidelines on LUTS suggestive of BPO (3) to the more contemporary and precise EAU Guidelines on Male LUTS, including BPO.

![Figure 1: Multifactorial aetiology of lower urinary tract symptoms (LUTS). The EAU Guidelines on Male LUTS mainly cover LUTS secondary to benign prostatic enlargement (BPE) or benign prostatic obstruction (BPO), detrusor overactivity or overactive bladder (OAB), and nocturia due to nocturnal polyuria. Other causes of male LUTS are covered by separate EAU Guidelines.](image-url)

Because patients seek help for LUTS and not an underlying attribute of the prostate such as BPH or BPE, these updated guidelines have been written from the perspective of men who complain about a variety of bladder storage, voiding and/or post-micturition symptoms. The recommendations made within the guidelines are based on the best available evidence. These recommendations apply to men aged 40 years or older who seek professional help for various forms of non-neurogenic benign forms of LUTS, e.g. LUTS/BPO, detrusor...
overactivity—overactive bladder (OAB), or nocturnal polyuria. Assessment and treatment of neurogenic LUTS has been published elsewhere and is valid only for men and women with bladder symptoms due to neurological diseases (4). EAU Guidelines on LUTS due to urinary incontinence, urogenital infections, ureteral stones, or malignant diseases of the lower urinary tract have been published elsewhere.

The recommendations of these guidelines are based on a structured literature search using articles in English language published in the PubMed/Medline, Web of Science, and Cochrane databases between 1966 and 1st January 2010, including the search terms “lower urinary tract symptoms”, “benign prostatic hyperplasia”, “detrusor overactivity”, “overactive bladder”, “nocturia”, and “nocturnal polyuria” in combination with the various treatment modalities and the search limits “humans”, “adult men”, “review”, “randomised clinical trials”, “clinical trials”, and “meta-analysis”. There have been no new drugs licensed since the literature search.

Language: English

Literature Search: conducted 1st February - 1st March 2010

Search Period: 1966 - 1st January 2010

<table>
<thead>
<tr>
<th>Search limits …</th>
<th>for group search terms …</th>
<th>in combination with investigated drugs, operations, or synonyms</th>
</tr>
</thead>
</table>

Each extracted article was separately analysed, classified, and labelled with a Level of Evidence (LE), according to a classification system modified from the Oxford Centre for Evidence-based Medicine in 2001 (LE: 1a, highest evidence level) to expert opinion (LE: 4, lowest evidence level) (5). Subsections for the various types of conservative treatments, drugs, and operations are presented in a homogeneous structure listing (1) “mechanism of action”, (2) “available drugs” with a table of key pharmacokinetic profiles or “operative procedure” in case of surgical intervention, (3) “efficacy” with a table of trials with the highest LE, (4) “tolerability and safety”, (5) “practical considerations”, and (6) “recommendations”, which were drawn from the relevant articles using a Grade of Recommendation (GR) according to a classification system modified from the Oxford Centre for Evidence-based Medicine, ranging from a strong (Grade A) to a weak (Grade C) recommendation. (5).

The working panel consisted of urologists, a pharmacologist, and an epidemiologist and statistician who have been working on the topic for the last 4 years. The guidelines are primarily written for urologists but can also be used by general practitioners, patients, or other stakeholders. The working panel intends to update the content and recommendations, according to the given structure and classification systems, every 2 years.

An update of these guidelines will be presented on the website of the EAU in the course of 2013. A complete revision will be included in the 2014 print version of the EAU Guidelines.

1.1 References

2. ASSESSMENT

Systematic diagnostic work-up should be done by history, validated symptom questionnaires (e.g. IPSS), both ideally proactively, physical examination, urinalysis, blood analysis, ultrasound (US) of the prostate, bladder and kidneys, uroflowmetry and US measurement of post-void residual urine, and bladder diary in cases of urinary frequency or nocturia. Only the diagnosis of nocturnal polyuria (> 33% of the 24-hour urine excretion overnight) can be made by the bladder diary, whereas the diagnosis of all other forms of non-neurogenic benign forms of LUTS in men aged 40 years or older is mainly made by exclusion. The systematic work-up should exclude relevant diseases or conditions also causing LUTS in adult men. An assessment algorithm is proposed in figure 2.

---

Figure 2: Assessment algorithm of LUTS in men aged 40 years or older. Systematic work-up can exclude other diseases or conditions also associated with LUTS. The assessment may be interrupted or stopped when relevant pathologies have been identified.
Benign prostatic obstruction and detrusor overactivity are urodynamic diagnoses. Filling cystometry and pressure-flow measurement are optional tests usually indicated before surgical treatment in men who:

- cannot void ≥ 150 mL;
- have a maximum flow rate ≥ 15 mL/s;
- are < 50 or > 80 years of age;
- can void but have post-void residual urine > 300 mL;
- are suspicious of having neurogenic bladder dysfunction;
- have bilateral hydronephrosis;
- had radical pelvic surgery or;
- had previous unsuccessful (invasive) treatment.

3. CONSERVATIVE TREATMENT

3.1 Watchful waiting - behavioural treatment
Many men with LUTS do not complain of high levels of bother and are therefore suitable for non-medical and non-surgical management - a policy of care known as watchful waiting (WW). It is customary for this type of management to include the following components: education, reassurance, periodic monitoring, and lifestyle advice. In many patients, it is regarded as the first tier in the therapeutic cascade and most men will have been offered WW at some point. Watchful waiting is a viable option for many men as few, if left untreated, will progress to acute urinary retention and complications such as renal insufficiency and stones (1,2). Similarly, some symptoms may improve spontaneously, while other symptoms remain stable for many years (3).

3.2 Patient selection
All men with LUTS should be formally assessed prior to starting any form of management in order to identify those with complications that may benefit from intervention therapy. Men with mild to moderate uncomplicated LUTS (causing no serious health threat), who are not too bothered by their symptoms, are suitable for a trial of WW. A large study comparing WW and transurethral resection of the prostate (TURP) in men with moderate symptoms showed that those who had undergone surgery had improved bladder function over the WW group (flow rates and post-void residual volumes), with the best results being in those with high levels of bother. Thirty-six per cent of patients crossed over to surgery in 5 years, leaving 64% doing well in the WW group (4). Approximately 85% of men will be stable on WW at 1 year, deteriorating progressively to 65% at 5 years (5, 6). The reason why some men deteriorate with WW and others do not is not well understood; increasing symptom bother and PVR volumes appeared to be the strongest predictors of failure.

3.3 Education, reassurance, and periodic monitoring
There now exists LE 1b that self-management as part of WW reduces both symptoms and progression (7, 8) (Table 1). In this study, men randomised to three self-management sessions in addition to standard care had better symptom improvement and improved quality of life at 3 and 6 months when compared to men treated with standard care only. These differences were maintained at 12 months. Nobody is quite sure which key components of self-management are effective, but most experts believe the key components are:

- education about the patient’s condition;
- reassurance that cancer is not a cause of the urinary symptoms;
- framework of periodic monitoring.

Table 1: Self-management as part of watchful waiting reduces symptoms and progression (7)

3.4 Lifestyle advice

The precise role of lifestyle advice in conferring benefit seen in the studies reported to date remains uncertain. Minor changes in lifestyle and behaviour can have a beneficial effect on symptoms and may prevent deterioration requiring medical or surgical treatment. Lifestyle advice can be obtained through informal and formal routes. If it is offered to men, it should probably comprise the following:

- Reduction of fluid intake at specific times aimed at reducing urinary frequency when most inconvenient, e.g. at night or going out in public. The recommended total daily fluid intake of 1500 mL should not be reduced.
- Avoidance or moderation of caffeine and alcohol which may have a diuretic and irritant effect, thereby increasing fluid output and enhancing frequency, urgency and nocturia.
- Use of relaxed and double-voiding techniques.
- Urethral stripping to prevent post-micturition dribble.
- Distraction techniques, such as penile squeeze, breathing exercises, perineal pressure and mental ‘tricks’ to take the mind off the bladder and toilet, to help control irritative symptoms.
- Bladder re-training, by which men are encouraged to ‘hold on’ when they have sensory urgency to increase their bladder capacity (to around 400 mL) and the time between voids.
- Reviewing a man’s medication and optimising the time of administration or substituting drugs for others that have fewer urinary effects.
- Providing necessary assistance when there is impairment of dexterity, mobility or mental state.
- Treatment of constipation.

3.5 Practical considerations

The components of self-management have not been individually subjected to study. The above components of lifestyle advice have been derived from formal consensus methodology (9). Further research in this area is required.

4. DRUG TREATMENT

4.1 \(\alpha_1\)-adrenoceptor antagonists (\(\alpha_1\)-blockers)

4.1.1 Mechanism of action

Historically, it was assumed that \(\alpha_1\)-blockers act by inhibiting the effect of endogenously released noradrenaline on prostate smooth muscle cells, thereby reducing prostate tone and bladder outlet obstruction. Contraction of the human prostate is mediated predominantly, if not exclusively, by \(\alpha_1\)A-adrenoceptors (1). However, it has been shown that \(\alpha_1\)-blockers have little effect on urodynamically determined bladder outlet resistance (2) and treatment-associated improvement of LUTS is correlated only poorly with obstruction (3). Hence, there has been a lot of discussion about the role of \(\alpha_1\)-adrenoceptors located outside the prostate (e.g. in the urinary bladder and/or spinal cord) and other \(\alpha\)-adrenoceptor subtypes (\(\alpha_1\)B- or \(\alpha_1\)D-adrenoceptors) as mediators of beneficial effects of \(\alpha_1\)-blockers. \(\alpha_1\)-adrenoceptors in blood vessels, other non-prostatic smooth muscle cells, and central nervous system are considered to be mediators of side-effects during \(\alpha\)-blocker treatment, and all three receptor subtypes seem to be involved. This concept has favoured the use of \(\alpha_1\)A-selective adrenoceptor antagonists. However, it remains to be determined whether \(\alpha_1\)A-selectivity is the only and main factor determining good tolerability.

4.1.2 Available drugs

Following the early use of phenoxybenzamine and prazosin in BPH-LUTS treatment, four \(\alpha_1\)-blockers are currently in mainstream use:

- alfuzosin HCL (alfuzosin);
- doxazosin mesylate (doxazosin);
- tamsulosin HCL (tamsulosin);
- terazosin HCL (terazosin).

Over a period of time, alfuzosin has been clinically available in Europe in three formulations, doxazosin and tamsulosin in two formulations each, and terazosin in one formulation (Table 2). Although different formulations result in different pharmacokinetic behaviours and, perhaps, tolerability profiles, the overall clinical impact of the different formulations is modest. Although some countries also have available indoramin, naftopidil and more recently silodosin, there have been only limited clinical data for these agents at the time of the literature search and, hence, they will not be discussed in these guidelines.

4.1.3 **Efficacy**

Indirect comparisons between α1-blockers, and limited direct comparisons, demonstrate that all α1-blockers have a similar efficacy in appropriate doses (4). Controlled studies have shown that α1-blockers typically reduce the International Prostate Symptom Score (IPSS), after a run-in period, by approximately 35-40% and increase the maximum urinary flow rate (Q\text{max}) by approximately 20-25% (Table 3). However, considerable improvements also occurred in the corresponding placebo arms (4,5). In open-label studies (without a run-in period), an IPSS improvement of up to 50% and Q\text{max} increase of up to 40% were documented (4,6).

Although these improvements take a few weeks to develop fully, statistically significant efficacy over placebo was demonstrated within hours to days. α1-blockers seem to have a similar efficacy, expressed as a percent improvement in IPPS, in patients with mild, moderate and severe symptoms (6). Prostate size does not affect α1-blocker efficacy in studies with follow-up periods of <1 year, but patients with smaller prostates (<40 mL) seem to have better efficacy compared to those with larger glands in longer-term and is similar across age groups (6). α1-blockers do not reduce prostate size and do not prevent acute urinary retention in long-term studies (8), so that eventually some patients will have to be surgically treated. Nevertheless, the efficacy of α1-blockers appears to be maintained over at least 4 years.

4.1.4 Tolerability and safety

Although alfuzosin, doxazosin, and terazosin are similar in terms of molecular structure and lack of α1-adrenoceptor subtype selectivity, the side-effect profile of alfuzosin is more similar to tamsulosin than to doxazosin and terazosin. The mechanisms underlying such differential tolerability are not fully understood, but may involve better distribution into lower urinary tract tissues by alfuzosin and tamsulosin. Other factors, such as subtype selectivity and the pharmacokinetic profiles of certain formulations, may also contribute to the tolerability profile of specific drugs.

The most frequent side-effects of α1-blockers are asthenia, dizziness and (orthostatic) hypotension. Although a reduction in blood pressure may benefit hypertensive patients, at least some of the observed asthenia and dizziness can be attributed to a decrease in blood pressure. Vasodilating effects are most pronounced with doxazosin and terazosin, and are much less common for alfuzosin and tamsulosin. The mechanisms underlying such differential tolerability are not fully understood, but may involve better distribution into lower urinary tract tissues by alfuzosin and tamsulosin. Other factors, such as subtype selectivity and the pharmacokinetic profiles of certain formulations, may also contribute to the tolerability profile of specific drugs.

Despite the long-standing and widespread use of α1-blockers, an adverse ocular event, termed intraoperative floppy iris syndrome (IFIS), has been discovered only recently in the context of cataract surgery (10). Although IFIS has been observed with all α1-blockers, most reports have been related to tamsulosin. Whether this reflects a greater risk with tamsulosin than with other α1-blockers, or rather its more widespread use, is not clear, particularly as the ratio between doses yielding ocular effects and those acting on the lower urinary tract are similar for all α1-blockers (11). It therefore appears prudent not to initiate α1-blocker treatment prior to cataract surgery, while existing α1-blocker treatment should be stopped though it is not clear how long before surgery takes place. It should be noted that the occurrence of IFIS complicates cataract surgery and makes it technically more demanding, however, there are no reports about increased health risks of these patients.

As LUTS and ED often co-exist, medical BPH treatment should not further impair sexual function. A systematic review concluded that α1-blockers do not adversely affect libido, have a small beneficial effect on erectile function, but sometimes cause abnormal ejaculation (12). Originally, the abnormal ejaculation...
was thought to be retrograde, but more recent data demonstrate that it is due to (relative) anejaculation, with young age being an apparent risk factor. Although abnormal ejaculation has been observed more frequently with tamsulosin than with other \(\alpha_1\)-blockers, this difference did not reach statistical significance in direct comparative studies with alfuzosin and is not associated with an overall reduction of overall sexual function (12). The apparently greater risk for abnormal ejaculation with tamsulosin is intriguing as even more \(\alpha_1\)-selective drugs, such as silodosin, carry a greater risk (13), however, all \(\alpha_1\)-blockers are dosed to block \(\alpha_1\)-adrenoceptors effectively. Hence, the mechanism underlying abnormal ejaculation remains to be elucidated.

4.1.5 Practical considerations
\(\alpha_1\)-blockers are often considered the first-line drug treatment of moderate-to-severe male LUTS. All \(\alpha_1\)-blockers are available in formulations, which are suitable for once-daily administration. To minimise adverse events, it is recommended that dose titration is used to initiate treatment with doxazosin and terazosin, however, this is not necessary with alfuzosin and tamsulosin. Because of their rapid onset of action, \(\alpha_1\)-blockers can be considered for intermittent use in patients with fluctuating intensity of symptoms not needing long-term treatment.

4.2 5α-reductase inhibitors

4.2.1 Mechanism of action
Androgen effects on the prostate are mediated by dihydrotestosterone (DHT), which is converted primarily in the prostatic stroma cells from its precursor testosterone by the enzyme 5α-reductase, a nuclear-bound steroid enzyme (1). Two isoforms of this enzyme exist:
• 5α-reductase type 1, with minor expression and activity in the prostate but predominant activity in...
extraprostatic tissues, such as skin and liver.

- 5α-reductase type 2, with predominant expression and activity in the prostate.

Finasteride inhibits only 5α-reductase type 2, whereas dutasteride inhibits 5α-reductase types 1 and 2 with similar potency (dual 5α-reductase inhibitor). However, the clinical role of dual inhibition remains unclear. 5α-reductase inhibitors act by inducing apoptosis of prostate epithelial cells (2) leading to prostate size reduction of about 18-28% and circulating PSA levels of about 50% after 6-12 months of treatment (3). Mean prostate volume reduction may be even more pronounced after long-term treatment.

### 4.2.2 Available drugs

Two 5α-reductase inhibitors are available for clinical use: dutasteride and finasteride (Table 4). The elimination half-time is longer for dutasteride (3-5 weeks). Both 5α-reductase inhibitors are metabolised by the liver and excreted in the faeces. Continuous treatment reduces the serum DHT concentration by approximately 70% with finasteride and 95% with dutasteride. However, prostate DHT concentration is reduced to a similar level (85-90%) by both 5α-reductase inhibitors.

</tbody>
</table>

<sub>t<sub>max</sub> = time to maximum plasma concentration; t½ = elimination half-life</sub>

### 4.2.3 Efficacy

Clinical effects relative to placebo are seen after minimum treatment duration of at least 6 to 12 months. After 2 to 4 years of treatment, 5α-reductase inhibitors reduce LUTS (IPSS) by approximately 15-30%, decrease prostate volume by approximately 18-28% and increase Q<sub>max</sub> of free uroflowmetry by approximately 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement (Table 5) (4-13).

Symptom reduction by finasteride depends on initial prostate size and may not be more efficacious than placebo in patients with prostates smaller than 40 mL (14). However, dutasteride seems to reduce IPSS, prostate volume, and the risk of acute urinary retention. It also increases Q<sub>max</sub> even in patients with prostate volumes between 30 and 40 mL at baseline (15,16). Indirect comparison between individual studies and one unpublished direct comparative trial indicate that dutasteride and finasteride are equally effective in the treatment of LUTS (3). Comparative studies with α<sub>1</sub>-blockers have demonstrated that 5α-reductase inhibitors reduce symptoms more slowly and, for finasteride, less effectively (5,10,17,18). A long-term trial with dutasteride in symptomatic men with a prostate volume greater than 30 mL (average prostate volume in the CombAT trial was approximately 55 mL) showed that the 5α-reductase inhibitor reduced LUTS in these patients at least as much or even more effectively than tamsulosin (11,12). The greater the baseline prostate volume (serum PSA concentration), the faster and more pronounced the symptomatic benefit of dutasteride (19). International prostate symptom score reduction was significantly greater in men with prostate volumes of 58 mL or more (PSA > 4.4) at treatment month 15 or later compared to men with lower baseline prostate volumes (PSA concentrations).

5α-reductase inhibitors, but not α<sub>1</sub>-blockers, reduce the long-term (> 1 year) risk of acute urinary retention or need for surgery (8,10,19,20). Prevention of disease progression by 5α-reductase inhibitors is already detectable with prostate sizes considerably smaller than 40 mL (12,13,20). The precise mechanism of action of 5α-reductase inhibitors in reducing disease progression remains to be determined, but it is most likely attributable to reduction of bladder outlet resistance. Open-label trials demonstrated relevant reductions of voiding parameters after computer-urodynamic re-evaluation in men who were treated at least 3 years with finasteride (21,22).

Qmax = maximum urinary flow rate (free uroflowmetry); IPSS = International Prostate Symptom Score; Boyarski Score; a = significant compared to baseline (indexed wherever evaluated); b = significant compared to placebo/active control.

4.2.4 Tolerability and safety
The most relevant adverse effects of 5α-reductase inhibitors are related to sexual function and include reduced libido, erectile dysfunction and, less frequently, ejaculation disorders, such as retrograde ejaculation, ejaculation failure, or decreased semen volume (3,10,13). The incidence of sexual dysfunction and other adverse events is low and even decreased with trial duration. Gynaecomastia (breast enlargement with breast or nipple tenderness) develops in approximately 1-2% of patients.

4.2.5 Practical considerations
Treatment with 5α-reductase inhibitors should only be considered in men with moderate-to-severe LUTS and enlarged prostates (> 40 mL) or elevated PSA concentrations (> 1.4 – 1.6 µg/L). Due to the slow onset of action, 5α-reductase inhibitors are only suitable for long-term treatment (many years). Their effect on the serum
PSA concentration needs to be considered for prostate cancer screening. Of interest, 5α-reductase inhibitors (finasteride) might reduce blood loss during transurethral prostate surgery, probably due to their effects on prostatic vascularisation (23).

4.3 Muscarinic receptor antagonists

4.3.1 Mechanism of action

The predominant neurotransmitter of the urinary bladder is acetylcholine that is able to stimulate muscarinic receptors (m-cholinoreceptors) on the surface of detrusor smooth muscle cells. However, muscarinic receptors are not only densely expressed on smooth muscle cells but also on other cell types, such as epithelial cells of the salivary glands, urothelial cells of the urinary bladder, or nerve cells of the peripheral or central nervous system. Five muscarinic receptor subtypes (M1-M5) have been described in humans, of which the M2 and M3 subtypes are predominantly expressed in the detrusor. Although approximately 80% of these muscarinic receptors are M2 and 20% M3 subtypes, only M3 seems to be involved in bladder contractions in healthy humans (1,2). The role of M2 subtypes remains unclear. However, in men with neurogenic bladder dysfunction and in experimental animals with neurogenic bladders or bladder outlet obstruction M2 receptors seem to be involved in smooth muscle contractions as well (3).

The detrusor is innervated by parasympathetic nerves which have their origin in the lateral columns of sacral spinal cord on the level S2-S4 which itself is modulated by supraspinal micturition centres. The sacral micturition centre is connected with the urinary bladder by the pelvic nerves which release acetylcholine after depolarisation. Acetylcholine stimulates postsynaptic muscarinic receptors leading to G-protein mediated calcium release in the sarcoplasmatic reticulum and opening of calcium channels of the cell membrane and,
finally, smooth muscle contraction. Inhibition of muscarinic receptors by muscarinic receptor antagonists inhibit/decrease muscarinic receptor stimulation and, hence, reduce smooth muscle cell contractions of the bladder. Antimuscarinic effects might also be induced or modulated by the urothelium of the bladder and/or by the central nervous system (4,5).

4.3.2 **Available drugs**
The following muscarinic receptor antagonists are licensed for treating overactive bladder/storage symptoms in men and women (Table 6):

- darifenacin hydrobromide (darifenacin);
- fesoterodine fumarate (fesoterodine);
- oxybutynin HCl (oxybutynin);
- propiverine HCl (propiverine);
- solifenacin succinate (solifenacin);
- tolterodine tartrate (tolterodine);
- trospium chloride.

This drug class is still officially contraindicated in men with BPH/BOO due to the possibility of incomplete bladder emptying or development of urinary retention.

IR = immediate release; ER = extended release (in some countries some manufacturers may have assigned different designators to the ER formulation). The gel and patch formulations of oxybutynin were not included in this table. All information is based on the most recent corresponding US Summary of Product Characteristics as accessed on 18.4.2012, except for propiverine where the corresponding German form was used. Detailed information on other pharmacokinetic parameters and its alterations with renal or hepatic impairment, on drug metabolism and on pharmacokinetic drug-drug interactions has been summarised (6). All data refer to use in adults; where applicable, pharmacokinetic properties may differ in pediatric populations.

³Higher exposure can occur in CYP 2D6 poor metabolisers.

bOnly the active metabolite 5-hydroxy-methyl-tolterodine is detectable in blood after oral administration of fesoterodine.

²T1/2 is age-dependent, values taken from (7).

4.3.3 **Efficacy**
Muscarinic receptor antagonists have been predominantly tested in females in the past because it was believed that LUTS in women are caused by the bladder and, therefore, have to be treated with bladder-specific drugs. In contrast, it was believed that LUTS in men are caused by the prostate and need to be treated with prostate specific drugs. However, there is no scientific data for that assumption (8). A sub-analysis of an open-label trial of 2,250 male or female patients with OAB symptoms treated with tolterodine showed that age but not gender has a significant impact on urgency, frequency, or urge incontinence (9).

The efficacy of the anticholinergic drug tolterodine, and lately also fesoterodine, was tested as a single agent in adult men with bladder storage symptoms (OAB symptoms) but without bladder outlet

obstruction (BOO) (Table 7). Maximum trial duration was 25 weeks, but most of the trials lasted for only 12 weeks. In open-label trials with tolterodine, daytime frequency, nocturia, urge incontinence, and IPSS were all significantly reduced compared to baseline values after 12-25 weeks (10,11). In an open-label study with \(\alpha_1\)-blocker nonresponders, each answer of the IPSS questionnaire was improved during tolterodine treatment irrespective of storage or voiding symptoms (10). Randomised, placebo-controlled trials demonstrated that tolterodine can significantly reduce urge incontinence and daytime or 24-hour frequency compared to placebo. It was also demonstrated that urgency related voiding is significantly reduced by tolterodine (12-14). Although nocturia, urgency, or IPSS were reduced in the majority of patients, these parameters did not reach statistical significance in most of the trials. However, if treatment outcome was stratified by PSA-concentration (prostate volume) tolterodine significantly reduced daytime frequency, 24h voiding frequency and IPSS storage symptoms in those men with PSA concentrations below 1.3 ng/mL, which was not the case in men with PSA concentrations of 1.3 ng/mL or more, indicating that men with smaller prostates might profit more from antimuscarinic drugs (15).

**IPSS** = International Prostate Symptom Score; \(^a\) = significant compared to baseline \((p < 0.01; indexed wherever evaluated); \(^b\) = significant compared to placebo \((p < 0.05); c = significant compared to fesoterodine 4 mg \((p < 0.05)\)

### 4.3.4 Tolerability and safety

Muscarinic receptor antagonists are generally well tolerated and associated with approx. 3-10% study withdrawals which were not significantly different compared to placebo in most of the studies. Compared to placebo, drug-related adverse events appear with higher frequencies for dry mouth (up to 16%), constipation (up to 4%), micturition difficulties (up to 2%) nasopharyngitis (up to 3%), and dizziness (up to 5%).

Increase of PVR urine in men without bladder outlet obstruction is minimal and not significantly different compared to placebo (0 to 5 mL vs. -3.6 to 0 mL). Nevertheless, fesoterodine 8 mg showed higher post-void residuals (+20.2 mL) compared to placebo (-0.6 mL) or fesoterodine 4 mg (+9.6 mL) (16). The incidence of urinary retention in men without BOO was comparable with placebo in trials with tolterodine (0
to 1.3 vs. 0 to 1.4%). In men under fesoterodine 8 mg treatment, 5.3% had symptoms suggestive of urinary retention that was higher compared to placebo or fesoterodine 4 mg (0.8% each). These symptoms appeared during the first 2 weeks of treatment and affected men aged 66 years or older.

In men with BOO, antimuscarinic drugs are not recommended due to the theoretical decrease of bladder strength which might be associated with PVR urine or urinary retention. A 12-week placebo-controlled safety study dealing with men who had mild to moderate BOO (median bladder outlet obstruction index, BOOI, in the placebo or tolterodine group 43 and 49 cm H2O, respectively) demonstrated that tolterodine significantly increased the amount of PVR urine (49 vs. 16 mL) but was not associated with increased events of acute urinary retention (3% in both study arms) (17). Urodynamic effects of tolterodine included significant larger bladder volumes to first detrusor contraction, higher maximum cystometric bladder capacity, and decreased bladder contractility index. Maximum urinary flow remained unchanged in both the tolterodine and placebo groups. This single trial indicated that the short-term treatment with antimuscarinic drugs in men with BOO is safe.

4.3.5 Practical considerations
Although studies in elderly men with LUTS and overactive bladder symptoms were exclusively carried out with tolterodine or fesoterodine it is likely that similar efficacy and adverse events will also appear with other antimuscarinic agents. Long-term studies on the efficacy of muscarinic receptor antagonists in men with LUTS are still missing, therefore, these drugs should be prescribed with caution, and regular re-evaluation of IPSS and PVR urine is advised.

4.3.7 References

4.4 **Plant extracts - Phytotherapy**

4.4.1 **Mechanism of action**

Phytotherapy comprises the medical use of various extracts of different plants. It remains controversial which components of the extracts are responsible for symptom relief in male LUTS. The most important compounds are believed to be phytosterols, ß-sitosterol, fatty acids, and lectins (1). In vitro studies have shown that plant extracts:

- have anti-inflammatory, antiandrogenic, or oestrogenic effects;
- decrease sexual hormone binding globulin (SHBG);
- inhibit aromatase, lipooxygenase, growth-factor stimulated proliferation of prostatic cells, α-adrenoceptors, 5α-reductase, muscarinic cholinoeceptors, dihydropyridine receptors, or vanilloid receptors;
- improve detrusor function;
- neutralise free radicals (1-3).

However, most in vitro effects have not been confirmed in vivo and the precise mechanisms of action of plant extracts remain unclear.

4.4.2 **Available drugs**

Herbal drug preparations are made of roots, seeds, pollen, bark, or fruits of a single plant (monopreparations); others combine the extracts of two or more plants to one pill (combination preparations). A large number of different plants are used for the preparation of extracts. The most widely used plants are:

- *Cucurbita pepo* (pumpkin seeds)
- *Hypoxis rooperi* (South African star grass)
- *Pygeum africanum* (bark of the African plum tree)
- *Secale cereale* (rye pollen)
- *Serenoa repens* (syn. *Sabal serrulata*; berries of the American dwarf palm, saw palmetto)
- *Urtica dioica* (roots of the stinging nettle).
Different producers use different extraction techniques, distribute active ingredients with different qualitative and quantitative properties, or combine two or more herbal compounds in one pill. The extracts of the same plant produced by different companies do not necessarily have the same biological or clinical effects so that the effects of one brand cannot be extrapolated to others (4). To complicate matters even, two different batches of the same producer might contain different concentrations of active ingredients and cause different biological effects (5). Thus, the pharmacokinetic properties can differ significantly between different plant extracts.

4.4.3 Efficacy
Each class of plant extract is discussed separately because of the above-mentioned reasons (Table 8). Whenever possible, the brand name is mentioned to demonstrate possible differences between products. In general, no phytotherapeutic agent has been shown to significantly reduce prostate size and no trial has proven reduction of BOO or decreased disease progression.

- **Cucurbita pepo**: Only one trial has evaluated the efficacy of pumpkin seeds extracts (Prosta Fink™ forte) in patients with BPH-LUTS (6). A total of 476 patients were randomly assigned to placebo or Prostat Fink™ forte. After a follow-up of 12 months, IPSS and daytime voiding frequency were significantly reduced in the pumpkin seed group. However, uroflowmetry parameters (Q\text{max}, PVR urine, prostate volume, PSA concentration, nocturia, or quality of life (QoL) Score were not statistically different between the groups.

- **Hypoxis rooperi**: These phytopharmacological extracts contain a mixture of phytosterols bonded with glycosides of which β-sitosterol is the most important compound (Harzol™, Azuprostat™). Four randomised, placebo-controlled trials with durations between 4 and 26 weeks were published and summarised in a Cochrane report (7). Daily doses of plant extracts ranged from 60 to 195 mg. Two trials evaluated symptoms (8,9) and all four trials investigated Q\text{max} and PVR urine. A meta-analysis calculated weighted mean differences of -4.9 IPSS points, +3.9 mL/s in terms of Q\text{max} and -28.6 mL in terms of PVR urine in favour of β-sitosterol. Prostate size remained unchanged in all trials. No further trials have been carried out since the Cochrane report was published in 2000.

- **Pygeum africanum**: A Cochrane report dealing with the clinical results of *Pygeum africanum* extracts (mono- or combination preparations) summarised the results of 18 randomised, placebo-controlled trials (10). Most trials used the *Pygeum africanum* extract Tadenan™. The meta-analysis comprised 1,562 men, but individual trials were small in size and lasted only between 30 and 122 days. Most trials were performed in the 1970s and 1980s and did not use validated questionnaires such as the IPSS. Men treated with *Pygeum africanum* were twice as likely to report symptom improvement (relative risk [RR] 2.07) compared to men treated with placebo. The mean weighted difference of Q\text{max} was +2.5 mL/s and of PVR volume -13.2 mL in favour of *Pygeum africanum*. No further trials have been published since the Cochrane report in 2002.

- **Secale cereale**: A Cochrane report dealt with the clinical results of the main *Secale cereale* product Cernilton™ and comprised 444 men who were enrolled in two placebo-controlled and two comparative trials (Tadenan™, Paraprost™) lasting between 12 and 24 weeks (11). Men treated with Cernilton™ reported that they were twice as likely to benefit from therapy compared to placebo (RR 2.4). However, there were no significant differences between Cernilton™ and placebo with regard to Q\text{max}, PVR urine, or prostate volume. No additional placebo-controlled trial with the mono preparation of *Secale cereale* has been published since the Cochrane report in 2000.

- **Sabal serrulata/Serenoa repens**: A recently updated Cochrane report summarised the clinical results of 30 randomised trials comprising 5,222 men (12). *Serenoa repens* (mainly Permixon™ or Prostasereene™) was compared as mono or combination preparations either with placebo, other plant extracts (*Pygeum africanum, Urtica dioica*), the 5-reductase inhibitor finasteride, or the α\text{-blocker} tamsulosin. Mean follow-up of these trials varied between 4 and 60 weeks. The Cochrane report concluded that *Serenoa repens* was not superior to placebo, finasteride, or tamsulosin with regard to IPSS improvement, Q\text{max} or prostate size reduction. Similar levels of IPSS or Q\text{max} improvements in trials with finasteride or tamsulosin might be interpreted as treatment equivalence (13). For nocturia, *Serenoa repens* was significantly better than placebo (mean weighted difference -0.78).

- **Urtica dioica**: Two trials investigated the efficacy of stinging nettle mono preparations compared to placebo (14,15). One trial investigated 246 men with BPH-LUTS over a period of 52 weeks (14); only IPSS decreased significantly in the phytotherapy group (Bazoton™ uno), whereas Q\text{max} and PVR urine were not statistically different between the groups at the end of the trial. The second trial investigated 620 patients with BPH-LUTS over a period of 26 weeks (15); IPSS, Q\text{max} and PVR urine significantly improved compared to placebo.

- **Combination preparations**: Trials have been carried out, especially with the extract combination of *Sabal serrulata* and *Urtica dioica* (PRO 160/120, Prostatgutt™ forte). A 24-weeks placebo-controlled trial investigated the efficacy of Bazoton™ uno compared to placebo, finasteride, or tamsulosin. Mean follow-up of these trials varied between 4 and 60 weeks. The Cochrane report concluded that Bazoton™ uno was not superior to placebo, finasteride, or tamsulosin with regard to IPSS improvement, Q\text{max} or prostate size reduction. Similar levels of IPSS or Q\text{max} improvements in trials with finasteride or tamsulosin might be interpreted as treatment equivalence (13). For nocturia, *Serenoa repens* was significantly better than placebo (mean weighted difference -0.78).
A 24-week open label extension trial of the same patients, in which all patients were treated with PRO 160/120, showed similar improvements of IPSS at week 48 in both groups (-7 IPSS points). A second trial, in which PRO 160/120 was randomised against finasteride, showed similar results for IPSS and Qmax in both groups (17).

IPSS = International Prostate Symptom Score; Qmax = maximal urinary flow rate (free uroflowmetry); PVR = post-void residual; n.s. = not significant; RR = relative risk
† absolute values; a = significant reduction compared to placebo/comparison treatment arm (p<0.05); b = in favour of plant extract.
4.4.4 **Tolerability and safety**

Side-effects during phytotherapy are generally mild and comparable to placebo with regard to severity and frequency. Serious adverse events were not related to study medication. Gastrointestinal complaints were the most commonly reported side-effects. In formulations with *Hypoxis rooperi*, ED appeared in 0.5% of patients. Trial withdrawals were almost equal in both placebo and phytotherapy groups.

4.4.5 **Practical considerations**

Phytotherapeutic agents are a heterogeneous group of plant extracts used to improve BPH-LUTS. Phytotherapy remains problematic to use because of different concentrations of the active ingredient(s) in different brands of the same phytotherapeutic agent. Hence, meta-analyses of extracts of the same plant do not seem to be justified and results of these analyses have to be interpreted with caution.

4.4.6 **Recommendations**

The guidelines committee is unable to make specific recommendations about phytotherapy of male lower urinary tract symptoms because of the heterogeneity of the products and the methodological problems associated with meta-analyses.

4.4.7 **References**

4.5 Vasopressin analogue - desmopressin

4.5.1 Mechanism of action

The antidiuretic hormone arginine vasopressin (AVP) plays a key role in body water homeostasis and the control of urine production by binding to the V2 receptor in the renal collecting ducts. Arginine vasopressin increases water re-absorption as well as urinary osmolality and decreases water excretion as well as total urine volume. Arginine vasopressin might be therapeutically used to manipulate the amount of urine excretion but, however, AVP also has V1 receptor mediated vasoconstrictive/hypertensive effects and a very short serum half-life, which makes the hormone unsuitable for the treatment of nocturia/nocturnal polyuria.

4.5.2 Available drugs

Desmopressin acetate (desmopressin) is a synthetic analogue of AVP with high V2 receptor affinity and antidiuretic properties. It is the only registered drug for antidiuretic treatment (Table 9). In contrast to AVP, desmopressin has no relevant V1 receptor affinity and hypertensive effects. Desmopressin may be used by intravenous infusion, nasal spray, tablet, or MELT formulation. Nasally or orally administered desmopressin is rapidly absorbed and, later, excreted 55% unchanged by the kidneys (1). Desmopressin has been used for over 30 years in the treatment of diabetes insipidus or primary nocturnal enuresis and has recently been approved in most European countries for the treatment of nocturia polyuria for adult male and female patients. After intake before sleeping, urine excretion during the night decreases and, therefore, the urge to void is postponed and the number of voids at night is reduced (2,3). The clinical effects - in terms of urine volume decrease and an increase in urine osmolality - last for approximately 8-12 hours (2).

$t_{\text{max}} = \text{time to maximum plasma concentration}; t_{\frac{1}{2}} = \text{elimination half-life}.$
4.5.3 Efficacy
The majority of clinical trials have used desmopressin in an oral formulation. A dose-finding study showed that the nocturnal urine volume/nocturnal diuresis was more reduced by oral desmopressin 0.2 mg than 0.1 mg; however, this study also showed that a 0.4 mg dose taken once before sleeping had no additional effects on the nocturnal diuresis compared to a 0.2 mg dose (4). In the pivotal clinical trials, the drug was titrated from 0.1 to 0.4 mg according to the individual clinical response. Desmopressin significantly reduced nocturnal diuresis by approximately 0.6-0.8 mL/min (-40%), decreased the number of nocturnal voids by approximately 0.8-1.3 (-40%) (-2 in the long-term open-label trial), and extended the time until the first nocturnal void by approximately 1.6 hours (-2.3 in the long-term open-label trial) (Table 10). Furthermore, desmopressin significantly reduced night-time urine volume as well as the percentage of urine volume excreted at night (5,8).

The clinical effects of desmopressin were more pronounced in patients with more severe nocturnal polyuria and bladder capacity within the normal range at baseline. The 24-hour diuresis remained unchanged during desmopressin treatment (6). The clinical effects were stable over a follow-up period of 10-12 months and returned to baseline values after trial discontinuation (12). A significantly higher proportion of patients felt fresh in the morning-time after desmopressin use (odds ratio 2.71) (11).

*Majority of study participants were men; ‡ only male data; a = significant compared to placebo.

4.5.4 Tolerability
The absolute number of adverse events associated with desmopressin treatment were higher compared to placebo but usually mild in nature. The most frequent adverse events in short-term (up to 3 weeks) and long-term studies (12 months) were headache, nausea, diarrhoea, abdominal pain, dizziness, dry mouth, and hyponatraemia. These events were comparable with the established safety profile of desmopressin in the treatment of polyuria due to other conditions. Peripheral oedema (2%) and hypertension (5%) were reported in the long-term treatment trial (12).

Hyponatraemia (serum sodium concentration < 130 mmol/L) was observed mainly in patients aged
65 years or older and seemed to occur less frequently in men compared to women of the same age (3). Hyponatraemia of all degrees, not necessarily associated with symptoms, occurs in approximately 5% (13) to 7.6% of patients (14) early after treatment initiation. The risk of developing hyponatraemia significantly increases with age (odds ratio 1.16 per year of age), lower serum sodium concentration at baseline (odds ratio 0.76), and higher basal 24-hour urine volume per bodyweight (odds ratio 1.09) (13). The chance of developing hyponatraemia in patients younger than 65 years is less than 1%, whereas the risk for older patients increases to 8% with normal sodium concentration and up to 75% in patients with low sodium concentration at baseline (13).

Therefore, the treatment of men aged 65 years or older should not be initiated without monitoring the serum sodium concentration. At the time of treatment initiation or dose change, older men with normal values of serum sodium should be monitored by Na⁺ measurement at day 3 and day 7 of treatment as well as at 1 month later. If serum sodium concentration has remained normal and no dose adjustment is intended, Na⁺ should be monitored every 3-6 months thereafter (15). Furthermore, patients should be informed about the prodromal symptoms of hyponatraemia, such as headache, nausea, or insomnia.

### 4.5.5 Practical considerations

Desmopressin should be taken once daily before sleeping. As the optimal dose differs between patients, desmopressin treatment should be initiated at a low dose (0.1 mg/day) and may be gradually increased every week until maximum efficacy is reached. The maximal daily dose recommended is 0.4 mg/day. Patients should avoid drinking fluids at least 1 hour before using desmopressin until 8 hours thereafter. In men aged 65 years or older, desmopressin should not be used if the serum sodium concentration is below the normal value. In all other men aged 65 years or older, serum sodium concentration should be measured at day 3 and 7 as well as after 1 month and, if serum sodium concentration has remained normal, every 3-6 months subsequently.

4.6 Combination therapies

4.6.1 \(\alpha_1\)-blockers + 5\(\alpha\)-reductase inhibitors

4.6.1.1 Mechanism of action

Combination therapy of \(\alpha_1\)-blockers and 5\(\alpha\)-reductase inhibitors aims to combine the differential effects of both drug classes to create synergistic efficacy in symptom improvement and prevention of disease progression.

4.6.1.2 Available drugs

Combination therapy consists of an \(\alpha_1\)-blocker (alfuzosin, doxazosin, tamsulosin, or terazosin; pharmacokinetic properties see Section 3.1.2) together with a 5\(\alpha\)-reductase inhibitor (dutasteride or finasteride; pharmacokinetic properties see Section 3.2.2). The \(\alpha_1\)-blocker exhibits clinical effects within hours or days, whereas the 5\(\alpha\)-reductase inhibitor needs several months to develop significant clinical efficacy. Of all drug combinations possible, so far finasteride together with alfuzosin, doxazosin, or terazosin, and dutasteride together with tamsulosin, have been tested in clinical trials. Both compounds show class effects with regard to efficacy and adverse events. No differences in pharmacokinetic or pharmacodynamic properties of the combined use of both drugs have been reported compared to single drug.

4.6.1.3 Efficacy

Several studies have investigated the efficacy of combination therapy against the efficacy of an \(\alpha_1\)-blocker, 5\(\alpha\)-reductase inhibitor, or placebo alone (Table 11). Initial studies with follow-up periods between 6 and 12 months used symptom (IPSS) change as their primary endpoint (1-3). These trials consistently demonstrated that the \(\alpha_1\)-blocker was superior to finasteride in symptom reduction, whereas the combination treatment was not superior to the \(\alpha_1\)-blocker alone. In studies which included a placebo arm, the \(\alpha_1\)-blocker was consistently more effective than placebo, whereas finasteride was consistently not more effective than placebo. Data from the 1-year time point of the MTOPS (Medical Therapy of Prostatic Symptoms) study, which have been published but not specifically analysed for this time point, showed similar results (4).

More recently, 4-year data analysis from MTOPS as well as the 2- and 4-year results from the CombAT (Combination of Avodart® and Tamsulosin) trials, have been reported (4-6). The latter trial included older men with larger prostates and higher serum PSA concentrations and therefore appears to represent men at greater risk of disease progression. In contrast to earlier studies with only 6 to 12 months follow-up, long-term data have demonstrated that combination treatment is superior to either monotherapy with regard to symptom reduction and Q\(\text{max}\) improvement and superior to \(\alpha_1\)-blocker in reducing the risk of acute urinary retention and the need for surgery (4-6). The CombAT study demonstrated that combination treatment is superior to either monotherapy with regard to symptom improvement and Q\(\text{max}\) starting from month 9 and superior to \(\alpha_1\)-blocker with regard to the reduction in the risk of acute urinary retention and the need for surgery after month 8 (6). The different results between the CombAT and MTOPS trials appear to arise from different inclusion and exclusion criteria rather than the types of \(\alpha_1\)-blockers or 5\(\alpha\)-reductase inhibitors. Dutasteride or finasteride alone reduced prostate volume as effectively as combination treatment (-20 to -27%).
Three studies addressed the issue of discontinuation of the $\alpha_1$-blocker (7-9). One trial evaluated the combination of tamsulosin with dutasteride and the impact of tamsulosin discontinuation after 6 months (7). After cessation of the $\alpha_1$-blocker, almost three-quarters of patients reported no worsening of symptoms. However, patients with severe symptoms (IPSS > 20) at baseline may benefit from longer combination therapy. A more recently published trial evaluated the symptomatic outcome of finasteride monotherapy at 3 and 9 months after discontinuation of 9-month combination therapy (finasteride plus $\alpha_1$-blocker) (8). LUTS improvement after combination therapy was sustained at 3 months (IPSS difference 1.24) and 9 months (IPSS difference -0.44).

In a retrospective study, the likelihood of $\alpha_1$-blocker discontinuation, which was based on the individual decision of the patient, was evaluated over a 12-month period in men aged > 65 years receiving $\alpha_1$-blockers in combination with either dutasteride or finasteride (9). Dutasteride patients discontinued $\alpha_1$-blocker therapy 64% faster than finasteride patients at any time point. At 12 months, 62% of patients were treated with dutasteride alone compared to 43.7% of men treated with finasteride alone.

Combination therapy was shown to be superior to monotherapy in both the MTOPS and CombAT trials in preventing overall clinical progression, as defined by an IPSS increase of at least 4 points, acute urinary retention, urinary tract infection (UTI), incontinence, or an increase in serum creatinine > 50% compared to baseline values. For combination therapy in the MTOPS trial versus the CombAT trial, the following reductions were observed:

- overall risk of disease progression was 66% versus 44%;
- symptomatic progression, 64% vs. 41%;
- acute urinary retention, 81% vs. 68%;
- urinary incontinence, 65% vs. 26%;
- BPH-related surgery, 67% vs. 71%.

Monotherapy with 5α-reductase inhibitor appeared to reduce the risks of acute urinary retention and prostate-related surgery as effectively as combination treatment (differences not significant), although the preventive effects were more pronounced with combination therapy (4,6). The MTOPS trial results suggested that the $\alpha_1$-blocker alone might also reduce the risk of symptom progression.

**Table 11: Randomised trials using $\alpha_1$-blocker, 5α-reductase inhibitor, and the combination of both drugs in men with LUTS and benign prostatic enlargement due to benign prostatic hyperplasia**

(Of note: references 5 and 6 reflect different time points of the same study.)

</table>
4.6.1.4  Tolerability and safety
In both the CombAT and MTOPS trials, overall drug-related adverse events were significantly more frequent during combination treatment than during either monotherapy. The adverse events observed during combination treatment were typical of an \( \alpha_1 \)-blocker and 5\( \alpha \)-reductase inhibitor. The frequencies of adverse events were significantly higher for combination therapy for most adverse events (4).

4.6.1.5  Practical considerations
Compared to \( \alpha_1 \)-blockers or 5\( \alpha \)-reductase inhibitor monotherapy, combination therapy results in a greater improvement in LUTS and increase in \( Q_{\text{max}} \), and is superior prevention of disease progression. However, combination therapy is also associated with more adverse events. Combination therapy should therefore be used primarily in men who have moderate to severe LUTS and are at risk of disease progression (higher prostate volume, higher PSA concentration, advanced age, etc.). Combination therapy should only be used when long-term treatment (more than 12 months) is intended; this issue should be discussed with the patient before treatment. Discontinuation of the \( \alpha_1 \)-blocker after 6 months might be considered in men with moderate LUTS.

4.6.1.6  Recommendations

| Combination treatment with \( \alpha_1 \)-blocker together with 5\( \alpha \)-reductase inhibitor should be offered to men with moderate-to-severe lower urinary tract symptoms, enlarged prostates (> 40 mL), and reduced \( Q_{\text{max}} \) (men likely to develop disease progression). Combination treatment is not recommended for short-term therapy (< 1 year). |

4.6.1.7  References

4.6.2 \(\alpha_1\)-blockers + muscarinic receptor antagonists

4.6.2.1 Mechanism of action
Combination therapy of an \(\alpha_1\)-blocker together with a muscarinic receptor antagonist aims to antagonize both \(\alpha_1\)-adrenoceptor and muscarinic cholinoreceptors (M2 and M3) in the lower urinary tract, hereby using the efficacy of both drug classes to achieve synergistic effects.

4.6.2.2 Available drugs
Combination treatment consists of an \(\alpha_1\)-blocker (alfuzosin, doxazosin, tamsulosin, or terazosin; pharmacokinetic properties chapter 3.1.2) together with a muscarinic receptor antagonist (darifenacin, fesoterodine, oxybutynin, propiverine, solifenacin, tolterodine, or trospium chloride; pharmacokinetic properties chapter 3.3.2). However, only the combinations of the \(\alpha_1\)-blocker doxazosin, tamsulosin, or terazosin and the muscarinic receptor antagonist oxybutynin, propiverine, solifenacin, or tolterodine have been tested in clinical trials so far. Until now, both drug classes have to be taken as separate pills as no combination pill is yet available. No differences in terms of pharmacokinetic or pharmacodynamic properties of the combined use of both drugs have been described compared to the use of the single drugs.

4.6.2.3 Efficacy
At least nine trials have been published investigating the efficacy of the combination treatment with \(\alpha_1\)-blockers and muscarinic receptor antagonists in adult male patients with LUTS (1-8). Additionally, one trial was published using the \(\alpha_1\)-blocker naftopidil (not registered in most European countries) with and without anticholinergic agents (9). Only one of those trials had a placebo arm (LE: 1b) and also tested the drug combination against the \(\alpha_1\)-blocker as well as against the muscarinic receptor antagonist (4); all other trials compared the efficacy of the combination therapy with the efficacy of an \(\alpha_1\)-blocker alone (Table 12) (LE: 2b). Maximum trial duration was 25 weeks but the majority of trials lasted 4-12 weeks only.

The combination of drugs was in general more efficacious in reducing voiding frequency, nocturia, or IPSS compared to \(\alpha_1\)-blockers or placebo alone. Furthermore, the combination treatment significantly reduced urge urinary incontinence episodes as well as urgency and significantly increased QoL (4).

Overall symptom improvement in the combination therapy arm was significantly higher compared to placebo regardless of PSA serum concentration, whereas tolterodine alone significantly improved symptoms predominantly in men with a serum PSA concentration less than 1.3 ng/mL (10). Three trials investigated the efficacy of combination treatment in patients with persistent LUTS during \(\alpha_1\)-blocker treatment by adding a muscarinic receptor antagonist to the existing \(\alpha_1\)-blocker therapy (add-on approach) (6-8). These trials demonstrated that persistent LUTS can be significantly reduced by the additional use of a muscarinic receptor antagonist (tolterodine) especially if detrusor overactivity had been demonstrated (Table 12). Patient reported QoL, treatment benefit, symptom bother, or patient perception of bladder condition was significantly improved in the combination treatment arm.

IPSS = International Prostate Symptom Score
† persisting LUTS during $\alpha_1$-blocker treatment (add-on approach)

<sup>a</sup> = significant compared to baseline ($p \leq 0.05$, indexed wherever evaluated)
<sup>b</sup> = significant reduction compared to placebo ($p < 0.05$)

4.6.2.4 Tolerability and safety

Adverse events of both drug classes appear during combination treatment of $\alpha_1$-blockers and muscarinic receptor antagonists. The most frequently reported side effect in all trials was xerostomia. Some side effects (e.g. xerostomia or ejaculation failure) appear with increased frequency and cannot simply be explained by adding the frequencies of adverse events of either drug. Post-void residual urine increased in most trials. Although the mean increase of PVR urine was low (+6 to +24 mL) some men developed higher PVRs or even urinary retention (0.9 to 3.3%). It remains unknown which men are at risk of developing PVR urine or urinary retention during the combination treatment.

4.6.2.5 Practical considerations

Class effects are likely to be responsible for increased efficacy and QoL in patients treated with $\alpha_1$-blocker and muscarinic receptor antagonist. Measuring of PVR urine is recommended during combination treatment to assess increase or urinary retention.
4.6.2.6 Recommendations

4.7 Emerging drugs

4.7.1 Phosphodiesterase (PDE) 5 Inhibitors (with or without $\alpha_1$-blockers)

4.7.1.1 Mechanism of action

Nitric oxide (NO) represents an important non-adrenergic, non-cholinergic neurotransmitter in the human body and is involved in signal transmission in the human urinary tract. Nitric oxide is synthesised from the amino acid L-arginine by NO synthases (NOS), which are classified based on their original tissues of detection as neuronal (nNOS), endothelial (eNOS), and immune cells (inducible NOS, iNOS). After being synthesised, NO diffuses...
into cells and stimulates the synthesis of cyclic guanosine monophosphate (cGMP) mediated by the enzyme guanylyl-cyclase. cGMP can activate protein kinases, ion channels, and cGMP-binding phosphodiesterases (PDEs) leading to smooth muscle cell relaxation via depletion of intracellular Ca\(^{2+}\) and desensitisation of contractile proteins (1). The effects of cGMP are terminated by PDE isoenzymes catalysing the hydrolysis of cGMP to an inactive form. Phosphodiesterase inhibitors increase the concentration and prolong the activity of intracellular cGMP; hereby reducing smooth muscle tone of the detrusor, prostate, and urethra. Until now, 11 different PDEs have been identified of which the PDEs 4 and 5 are the predominant ones in the transition zone of the human prostate, bladder, and urethra (2,3). Nitric oxide might also be involved in the micturition cycle by inhibiting reflex pathways in the spinal cord and neurotransmission in the urethra, prostate, or bladder (4).

4.7.1.2 Available drugs
Three selective oral PDE5Is (sildenafil citrate [sildenafil], tadalafil, and vardenafil hcl [vardenafil]) have been licensed in Europe for the treatment of ED or pulmonary arterial hypertension (sildenafil and tadalafil), but these drugs have not yet been officially registered for the treatment of male LUTS (Table 13). The available PDE5Is differ primarily in their pharmacokinetic profiles (5). All PDE5Is are rapidly resorbed from the gastrointestinal tract, have a high protein binding in plasma, and are metabolised primarily by the liver and eliminated predominantly by the faeces. However, their half-lives differ markedly. PDE5Is are taken on-demand by patients with erectile dysfunction but tadalafil is also registered for daily use in lower dose (5 mg) than for on-demand use.

Table 13: PDE5Is licensed in Europe for treating erectile dysfunction; key pharmacokinetic properties and doses used in clinical trials

\(t_{\text{max}}\) = time to maximum plasma concentration; \(t_{\frac{1}{2}}\) = elimination half-life; * dependent on food intake (i.e. slower resorption of the drug and an increase in \(t_{\text{max}}\) by approximately 1 hour after a fatty meal).

4.7.1.3 Efficacy
A post-hoc analysis of patients with ED treated with sildenafil initially showed that the PDE5I was capable of significantly reducing concomitant LUTS and increasing bladder symptoms-related QoL, as measured by the IPSS questionnaire (6,7). LUTS improvement was found to be independent of improvement of erectile function. Randomised, placebo-controlled trials on the efficacy of all three available oral PDE5Is have been published during the last years and have investigated changes in symptoms (IPSS), uroflowmetry parameters (Q\(_{\text{max}}\)), and PVR urine (6-16). The maximum trial duration was 12 weeks. These trials demonstrated that all PDE5Is significantly and consistently reduced IPSS by approximately 17-35% (Table 14). Both bladder storage and voiding symptoms decreased equally during treatment with PDE5Is. Post-void residual urine remained unchanged in most of the trials. Q\(_{\text{max}}\) of free uroflowmetry increased in a dose-dependent fashion (tadalafil [16]), but was not significantly different to placebo (sildenafil, tadalafil, and vardenafil). In contrast to the EBM level 1b-trials listed in Table 14, two singlecentre uroflowmetry studies documented improvements of Q\(_{\text{max}}\) and Q\(_{\text{ave}}\) following oral administration of 50 or 100 mg sildenafil in up to 76% of men (mean Q\(_{\text{max}}\) increase 3.7-4.3 mLs or 24-38%) (17,18). Phosphodiesterase 5 inhibitors significantly improved QoL compared to placebo-treated patients.

Three trials compared the efficacy of PDE5Is (sildenafil or tadalafil) with or without \(\alpha_1\)-blockers (alfuzosin or tamsulosin) (9,12,13). These trials were conducted in a small number of patients and with a limited follow-up of 6 to 12 weeks. The drug combination improved IPSS, Q\(_{\text{max}}\), and PVR urine to a greater extent than the single drug alone of each class (Table 14), although the difference compared to PDE5I or \(\alpha_1\)-blocker alone was only statistically significant in one of the three trials (12).

IPSS = International Prostate Symptom Score; Qmax = maximum urinary flow rate during free uroflowmetry; PVR = post-void residual; ‡ trial included patients with both ED and LUTS; * significant compared to placebo (p ≤ 0.05); † significant compared to baseline (p ≤ 0.05 (indexed wherever evaluated); ‡ significant compared to α1-blocker (tamsulosin, p < 0.05).
4.7.1.4 Tolerability and safety
Phosphodiesterase 5 inhibitors in general can cause headache, flushing, dizziness, dyspepsia, nasal congestion, myalgia, hypotension, syncope, tinnitus, conjunctivitis, or altered vision (blurred, discoloration). However, the frequencies of side-effects vary between the individual PDE5Is. The probability of developing priapism or acute urinary retention is considered minimal.

Phosphodiesterase 5 inhibitors are contraindicated in patients using nitrates or the potassium channel opener, nicorandil, due to additional vasodilatation, which might cause hypotension, myocardial ischaemia in patients with coronary artery disease, or cerebrovascular strokes (5). Additionally, all PDE5Is should not be used in patients who are taking the α₁-blockers doxazosin or terazosin, have unstable angina pectoris, have had a recent myocardial infarction (previous 3 months) or stroke (previous 6 months), myocardial insufficiency NYHA > 2, hypotension, poorly controlled blood pressure, significant hepatic or renal insufficiency, or if non-arteritic anterior ischemic optic neuropathy (NAION) with sudden loss of vision is known or has appeared after previous use of PDE5Is. Sildenafil and vardenafil are also contraindicated in patients with retinitis pigmentosa. Caution is advised if PDE5Is are used together with other drugs which are metabolised by the same hepatic elimination pathway (CYP3A4), which is associated with an increased serum concentration of the PDE5I.

4.7.1.5 Practical considerations
To date, PDE5Is have been officially licensed only for the treatment of ED and pulmonary arterial hypertension. Treatment beyond this indication (e.g. male LUTS) is still experimental and should not be used routinely in the clinical setting. Long-term experience in patients with LUTS is still lacking. The value of PDE5Is in the context of other available potent drugs (e.g. α₁-blockers, 5α-reductase inhibitors, or muscarinic receptor antagonists) remains to be determined. Insufficient information is available about combinations between PDE5Is and other LUTS medications.

4.7.1.7 References

4.7.2 **Other new drugs**

Several new drugs are currently under clinical investigation (phase II-III trials) of which none have been licensed for male LUTS so far. These new drugs target:

- the prostate, e.g. gonadotrophin-releasing hormone antagonists, oestrogen receptor antagonists, apoptosis-inducing agents, vaccines, vitamin D agonists, or androgen replacement therapies;
- the bladder, e.g. β3-adrenoceptor agonists;
- the nervous system, e.g. neuromuscular blocking agents, tachykinin receptor antagonists. Published results of those drugs are preliminary and sparse. Therefore, these new drugs were excluded from further analyses, but will be re-evaluated for the next version of the guidelines on male LUTS.
5. **SURGICAL TREATMENT**

5.1 **Transurethral Resection of the Prostate (TURP) and Transurethral Incision of the Prostate (TUIP)**

5.1.1 **Mechanism of action**

Transurethral resection of the prostate (TURP) was first performed in 1932. Whereas the material has changed substantially since the first procedure, the basic principle of TURP has remained unchanged. It is still, firstly, the removal of tissue from the transition zone of the prostate to reduce BPO and, secondly, to reduce LUTS.

Transurethral resection of the prostate is still regarded as the gold standard for the treatment of LUTS secondary to BPO in prostates between 30 and 80 mL. However, there is no strong evidence in the literature regarding the upper size limit of the prostate suitable for TURP. The suggested threshold sizes reflect the Panel's opinion that has assumed that this limit depends on the surgeon's experience, resection speed, and resectoscope sizes. During the last decade, there has been a continuous decline in the rate of TURPs performed. In 1999, TURP represented 81% of all surgery for benign prostatic hypertrophy (BPH) in the USA, but by 2005, TURP represented only 39% of surgical procedures for BPH, due to the combined effect of fewer prostatic operations and more minimally-invasive procedures (1).

Transurethral incision of the prostate (TUIP) was initially described by Orandi in 1969. TUIP reduces LUTS secondary to BPO by splitting the bladder outlet without tissue removal. This technique has been rediscovered and may replace TURP as the first choice of treatment in selected men with benign prostate enlargement, especially men with prostate sizes < 30 mL and without prostate middle lobes.

5.1.2 **Operative procedure**

During TURP, hyperplastic prostatic tissue of the transition zone is removed endoscopically using special resectoscopes and cutting loops, which enable ablation of prostatic tissue in small slices that are then removed from the bladder at the end of surgery. The cutting of prostatic tissue and coagulation of blood vessels is achieved by using adaptable electrical current.

During the TUIP procedure, one or two cuts are made into the prostatic parenchyma and capsule, thereby reducing urethral resistance (BPO). The technique has been modified by several authors. The most popular unilateral incision is located at the 6 o’clock position and the most commonly performed bilateral incisions are at the 5 and 7 o’clock positions.

Urinary tract infections (UTIs) should be treated prior to TURP or TUIP (2,3). The routine use of prophylactic antibiotics in TURP has been well evaluated with a considerable number of RCTs. Three systematic reviews of the available RCTs resulted in similar conclusions favouring the use of antibiotic prophylaxis (4-6). Antibiotic prophylaxis significantly reduces bacteriuria, fever, sepsis, and the need for additional antibiotics after TURP. There was also a trend towards higher efficacy in favour of short-course antibiotic administration than for a single-dose regimen (4). However, further studies are required to define the optimal antibiotic regimen and cost-effectiveness of antibiotic prophylaxis in TURP.

5.1.3 **Efficacy**

5.1.3.1 **Symptom improvement**

Transurethral resection of the prostate provides durable clinical outcomes, as shown by studies with a long follow-up of 8-22 years. There are no similar data on durability for any other surgical treatment for BPO (7). One study with a mean follow-up of 13 years reported a significant and sustained decrease in most symptoms and improvements in urodynamic parameters following TURP. The study also found that subjective and objective failures were associated with decreased detrusor contractility rather than BPO (8). A study in 577 men who underwent TURP reported excellent functional outcomes with a mean IPSS of 4.9 and a mean QoL score of 1.2 after 10 years of follow-up (9). A meta-analysis of 29 RCTs reported a mean LUTS improvement of 70.6% (95% CI: 66.4-75.5%) after TURP (10).

5.1.3.2 **RCT comparison of TUIP with TURP**

Eleven RCTs comparing TUIP with TURP are currently available (10-14) (Table 15). These studies evaluated similar LUTS improvements in patients with small prostates (< 20-30 mL) and no prostate median lobe (10-14). The findings are reported below.

Uroflowmetry: the mean Q\(_{\text{max}}\) increase following TURP was 125% with an absolute mean improvement of +9.7 mL/s (95% CI: 8.8-11.2 mL/s) (10). All RCTs comparing TUIP with TURP 12 months after the procedure reported a lower mean or median Q\(_{\text{max}}\) following TUIP with an overall mean Q\(_{\text{max}}\) improvement of 70% (95% CI: 27-112) (10,13).

Post-void residual: PVR volume decreased by 60.5% (95% CI: 48-71) after TURP (10). The decrease in PVR after TUIP varied across available studies, but was always lower than with TURP (10,13).

Re-treatment rate: a second prostatic operation, usually performed as TURP again, was reported at a
constant rate of approximately 1-2% per year. The review analysing 29 RCTs found a re-treatment rate of 2.6% (95% CI: 0.5-4.7) after a mean follow-up of 16 months (10). In a recent large-scale study of 20,671 men, who underwent TURP in Austria, the overall reported re-treatment rates (including secondary TURP, urethrotomy, and bladder neck incision) were 5.8%, 12.3%, and 14.7% at 1, 5, and 8 years of follow-up, respectively (14). The incidence of secondary TURP was 2.9%, 5.8%, and 7.4% for the same follow-up periods (14). Analyses of RCTs comparing TURP with TUIP showed that re-treatment was more likely following TUIP (17.5%) than after TURP (9%) (13).

5.1.4 Tolerability and safety

5.1.4.1 Intra- and peri-operative complications
Mortality following prostatectomy has decreased constantly and significantly during the past decades and is less than 0.25% in contemporary series (10,15,16). In the most recent study of 10,564 men who underwent TURP, peri-operative mortality (during the first 30 days) was 0.1% (17). The risk of transurethral resection (TUR) syndrome has also decreased during the last decades to less than 1.1% (10,16). Risk factors associated with TUR syndrome are excessive bleeding with opening of venous sinuses, prolonged operation time, large prostates, and past or present nicotine abuse (17). No cases of TUR syndromes were recorded in patients undergoing TUIP. The incidence of blood transfusion following TURP in the analysis of 29 RCTs was 8.4% (95% CI: 3.9-13.4) (10). Contemporary real-life data from 10,564 TURP procedures reported procedure-related bleeding requiring blood transfusion in 2.9% of patients. The risk of bleeding following TUIP is negligible (10).

5.1.4.2 Long-term risk of mortality
The possibility of an increased long-term risk of mortality after TURP compared to open surgery has been raised by Roos et al. (15). However, these findings have not been replicated by others (18-20). Recently, data from 20,671 TURPs and 2,452 open prostatectomies (OP) showed that the 8-year incidence of myocardial infarction was identical after TURP (4.8%) and OP (4.9%). Similarly, mortality rates at 90 days (0.7% vs. 0.9%), one year (2.8% vs. 2.7%), 5 years (12.7% vs. 11.8%) and 8 years (20% vs. 20.9%) were almost identical (14).

5.1.4.3 Long-term complications
Urinary incontinence: the median probability of postoperative stress urinary incontinence ranges from 1.8% following TUIP to 2.2% following TURP (1-6,13,15). A meta-analysis of three trials investigating urinary incontinence showed no statistically significant difference between the TUIP and TURP groups, although there were fewer events in the TUIP group (13).

Urinary retention and UTIs: a recent meta-analysis found no statistically significant differences between TURP and TUIP in the development of urinary retention and UTIs (13).

Bladder neck stenosis and urethral stricture: the risk of developing urethral strictures after TURP is 3.8% (95% CI: 1.7-5.8) and after TUIP 4.1% (10). The risk of bladder neck stenoses is 4.7% (95% CI: 0.3-9.2) after TURP (10). A systematic review reported an overall incidence of 8.7% for strictures after TUIP, but did not distinguish between urethral strictures and bladder neck stenoses (13).

Sexual function: retrograde ejaculation results from resection/destruction of the bladder neck and is reported by 65.4% (95% CI 53.4-77.5) of patients after TURP and 18.2% after TUIP (10). There is a longstanding controversy on the impact of prostatectomy, particularly TURP, on erectile function. The only RCT that compared TURP to a ‘wait and see’ policy with a follow-up of 2.8 years reported identical rates of ED in both arms (19% and 21%, respectively) (21). In the analysis of 29 RCTs, the incidence of ED following TURP was 6.5% (95% CI: 0.2-12.7%) (10). The frequently reported increase in ED after TURP seems to be caused by confounding factors (e.g. age) rather than being the direct consequence of TURP.

5.1.5 Practical considerations
TURP and TUIP are both effective primary treatments for men with BPO, BPE, and moderate-to-severe LUTS. The choice between TURP and TUIP should be primarily based on prostate volume, with prostates < 30 mL being mainly considered for TUIP and prostates of 30-80 mL for TURP. The advantages of TUIP are reduced bleeding incidents, shorter operation time, avoidance of TUR syndrome, minimal and shorter postoperative bladder irrigation, low risk of retrograde ejaculation, and shorter times for catheterisation and hospitalisation. The disadvantages are a higher rate of symptom recurrence and the need for additional surgery.

5.1.6 Modifications of TURP: bipolar Transurethral Resection of the Prostate

5.1.6.1 Mechanism of action
One of the most important recent improvements in TURP is the incorporation of plasmakinetic bipolar technology (B-TURP). To date, five types of bipolar resection devices have been developed: the plasmakinetic (PK) system (Gyrus), Vista Coblation/CTR (controlled tissue resection) system (ACMI) [withdrawn], transurethral resection in saline (TURis) system (Olympus), Karl Storz, and Wolf (22). The devices differ in the way in which
bipolar current flow is delivered to achieve the plasmakinetic effect.

5.1.6.2 Operative procedure
Prostatic tissue removal during B-TURP is identical to monopolar TURP. In contrast to monopolar TURP, B-TURP uses a specialised resectoscope loop, which incorporates both the active and return electrodes. It permits electrosurgical tissue cutting in a conductive saline medium. After activation of the high frequency current, the physiological saline around the loop is heated up to the boiling point. The resulting bubbles create an environment with high electrical resistance; the voltage between electrode and saline solution spikes forms an arc. The tissue is heated indirectly by the heat of the ignition of the arc; this enables both resection and coagulation. As with other endoscopic operations, UTIs should be treated before the procedure and prophylactic antibiotic therapy is advised.

5.1.6.3 Efficacy
The efficacy of bipolar TURP devices has been demonstrated in case series and RCTs. Three systematic reviews have provided important information on the efficacy of bipolar TURP (23-25). Almost identical outcomes were reported with monopolar and bipolar TURP concerning the improvement of $Q_{\text{max}}$ (10.5 mL/s vs. 10.8 mL/s) and the AUA-SS/IPSS (-15.2 vs. -15.1) (23).

Long-term results of B-TURP are still awaited. In an RCT comparing B-TURP with plasmakinetic energy with a mean follow-up of 18.3 months, the re-operation rate was 4.1% and 2.1% for the PK system and TURP, respectively (26). In a recent study with a follow-up of 3 years, the initially observed significant improvements remained durable for the bipolar and monopolar arm in terms of IPSS (6.8 vs. 6.2) and $Q_{\text{max}}$ (20.5 vs. 21.5 mL/s) (27).

5.1.6.4 Tolerability and safety
The overall rate of adverse events was significantly lower with B-TURP compared to monopolar TURP (28.6% vs. 15.5%) (23). Main advantages of B-TURP include reduced blood loss and decreased incidences of postoperative clot retention and blood transfusions. Both postoperative catheterisation and hospitalisation times were shorter with bipolar TURP compared to monopolar TURP; this was thought to be due to reduced bleeding associated with improved coagulation abilities. Postoperative storage symptoms, particularly dysuria, were less common with B-TURP. However, most of these results were trends favouring B-TURP rather than statistically significant differences (23).

TUR syndrome has not been reported with B-TURP, due to the use of physiological saline irrigation fluid and reduced fluid absorption during the procedure (23,24). Several RCTs have suggested that urethral strictures are more common with B-TURP with possible contributory factors being a larger resectoscope size (27F), the type of return electrode, and higher current densities (22). However, the most recent systematic review of RCTs did not reveal statistically significant differences between monopolar and bipolar TURP treatment arms (1.7% vs 2.4, respectively, $p = 0.280$) (24). Nevertheless, larger studies with increased numbers of patients and/or longer follow-ups may change these results. Regarding the impact of B-TURP on sexual function, it was found that postoperative retrograde ejaculation (57 vs 60%) (24) or ED (both about 14%) (23) did not differ significantly between B-TURP and monopolar TURP.

5.1.6.5 Practical considerations
B-TURP offers an attractive alternative to monopolar TURP in patients with LUTS secondary to BPO with similar efficacy but lower morbidity. Furthermore, the safety of B-TURP allows more time for training and teaching of urology residents. However, since there remains a lack of sufficient long-term data, it is not possible to draw definite conclusions about the duration of improvements and advantages of B-TURP over monopolar TURP. The choice of B-TURP should currently be based on the availability of the bipolar armamentarium, the surgeon’s experience, and the patient’s preference.
5.1.7  **Recommendations**

Monopolar TURP is the current surgical standard procedure for men with prostate sizes of 30-80 mL and moderate-to-severe LUTS secondary to BPO. Monopolar TURP provides subjective and objective improvement rates superior to medical or minimally invasive treatments. However, the morbidity of monopolar TURP is higher than for transur, bipolar TURP, drugs, or other minimally-invasive procedures.

Bipolar TURP achieves short-term results comparable to monopolar TURP.

TUIP is the surgical therapy of choice for men with LUTS secondary to BPO and prostate sizes < 30 mL without middle lobes.

---

5.2 Open prostatectomy

5.2.1 Mechanism of action

Open prostatectomy is the oldest surgical treatment modality for LUTS secondary to BPO. Obstructive prostatic adenomas are enucleated using the index finger, either from the inside of the bladder (Freyer procedure) or through the anterior prostatic capsule (Millin procedure), allowing unobstructed voiding.
5.2.2 Operative procedure

Indications for surgery

The most frequent indication for surgical management is bothersome LUTS refractory to medical management (1,2). The following complications of BPH/BPE/BPO are considered strong indications for surgery:

• refractory urinary retention;
• recurrent urinary infection;
• recurrent haematuria refractory to medical treatment with 5-alpha reductase inhibitors;
• renal insufficiency due to BPE/BPO;
• bladder stones.

Increased PVR volume may also be used as an indication for surgery. However, there is great intra-individual variability and an upper limit requiring intervention has not been defined. Variables most likely to predict the outcome of prostatectomy are severity of LUTS, the degree of bother, and the presence of BPO.

Procedure

A transurethral balloon catheter is inserted and the bladder is filled with saline solution. Access to the bladder or anterior prostatic capsule is obtained through a midline or transverse suprapubic incision.

Transvesical procedure (Freyer)

A transverse incision is made in the anterior bladder wall. The index finger is then placed in the urethra and with forward pressure towards the symphysis, the urethral mucosa is broken, and the plane between the surgical capsule and the adenomas is defined. The prostatic adenomas are then bluntly separated from the capsule with the finger. Special care must be taken when dividing the urethra at the apex in order not to harm the urethral sphincter. Haemostatic sutures are placed in the posterior corners of the cavity and the posterior margin, taking care not to include the ureteral orifices. Postoperative haemostasis might be obtained using gauze packing and/or traction on a large balloon catheter. For sufficient drainage, both a transurethral and a suprapubic catheter are placed.

Transcapsular procedure (Millin)

A transverse incision is made in the anterior prostatic capsule and the adenomas freed bluntly with a scissors and the index finger. Care is taken when dividing the urethra. Many surgeons will resect the posterior bladder neck to avoid late bladder neck stricture. The prostatic capsule is closed after insertion of a transurethral balloon catheter for drainage.

Peri-operative antibiotics

A known UTI should be treated before surgery (10,11). The routine use of prophylactic antibiotics remains controversial. However, antibiotics are recommended in patients on catheterisation prior to surgery.

5.2.3 Efficacy

Open prostatectomy is the treatment of choice for large glands (> 80-100 mL). Associated complications include large bladder stones or bladder diverticula (4-6). Three recent RCTs have shown that Holmium laser enucleation and PVP lead to similar outcomes compared to open prostatectomy in men with large glands (> 70, 80 and 100 mL) at a significantly lower complication rate (7-9).

5.2.3.1 Treatment outcome

The results of open prostatectomy studies for treating BPH-LUTS or BPO are summarised in Table 16.

• LUTS: open prostatectomy results in an improvement of LUTS of 63-86% and in the IPSS Quality of Life score of 60-87% (8,9,12).
• Uroflowmetry: the mean increase of $Q_{\text{max}}$ following open prostatectomy is 375% (range, 88-677%) (8,9,12) in absolute terms +16.5-20.2 mL/s (6,8,9,12).
• PVR: a reduction of 86-98% is seen in the PVR volume after open prostatectomy (8,9,12).

5.2.3.2 Long-term outcome and re-treatment rate

A favourable long-term outcome is common after open prostatectomy. A secondary prostatic operation has not been reported in the open prostatectomy arm in randomised studies up to 5 years follow-up (8,9,12) (Table 17).
5.2.4 **Tolerability and safety**

*Intra-/peri-operative complications*

Mortality following open prostatectomy has decreased significantly during the past two decades and is less than < 0.25% in contemporary series (13) (Table 17). The estimated need for blood transfusion following is about 7-14% (9,12,13).

*Long-term complications*

Long-term complications are incontinence and bladder neck contracture and urethral stricture. The risk of developing stress incontinence is up to 10% (4), while the risk for developing bladder neck contracture and urethral stricture is about 6% (7-9).

5.2.5 **Practical considerations**

Open prostatectomy is the most invasive, but also the most effective and durable, procedure for the treatment of LUTS secondary to BPO. Only Holmium enucleation delivers similar results, but with less morbidity. In the absence of an endourological armamentarium and a Holmium laser, open prostatectomy appears to be the treatment of choice for men with prostates > 80-100 mL and drug-treatment-resistant LUTS secondary to BPO. The choice between the Freyer or Millin procedures depends upon the surgeon’s preference.

BPO = benign prostatic obstruction

5.2.6 **Recommendations**

Open prostatectomy is the first choice of surgical treatment in men with drug-refractory LUTS secondary to benign prostatic obstruction and prostate sizes > 80-100 mL in the absence of Holmium lasers.

LUTS = lower urinary tract symptoms
5.2.7 References

5.3 Transurethral Microwave Therapy (TUMT)

5.3.1 Mechanism of action

Microwave thermotherapy of the prostate works by emitting microwave radiation through an intra-urethral antenna in order to deliver heat into the prostate. Tissue is destroyed by being heated at temperatures above cytotoxic thresholds (> 45°C) (coagulation necrosis). Heat is mainly produced by electrical dipoles (water molecules) oscillating in the microwave field and electric charge carriers (ions) moving back and forth in the microwave field. It is also thought that the heat generated by TUMT also causes apoptosis and denervation of α1-receptors, thereby decreasing the smooth muscle tone of the prostatic urethra.

5.3.2 Operative procedure

Transurethral microwave therapy is a registered trademark of Technomed Medical Systems, the pioneer of microwave thermotherapy. Currently, the main devices in the field of microwave thermotherapy are the Prostatron™ device (Urologix, Minneapolis, MN, USA), Targis™ (Urologix, Minneapolis, MN, USA), CoreTherm™ (ProstaLund, Lund, Sweden), and TMx-2000™ (TherMatrx Inc, Northbrook, ILL, USA). Most published data on thermotherapy has been on the Prostatron device.
Conceptually, TUMT devices are all similar in delivering microwave energy to the prostate with some type of feedback system. All TUMT devices consist of a treatment module that contains the microwave generator with a temperature measurement system and a cooling system. The main difference between TUMT devices is the design of the urethral applicator. The applicator consists of a microwave catheter connected to the module, which is inserted into the prostatic urethra. Differences in the characteristics of applicators have a significant effect on the heating profile (1). Other less important differences between TUMT devices are found in the catheter construction, cooling systems, treatment time, and monitoring of TUMT effects (2).

5.3.3  Efficacy

5.3.3.1  Clinical outcome

A systematic review of all available RCTs on TUMT attempted to assess therapeutic efficacy (Table 18) (3) in different TUMT devices and software, including Prostatron (Prostatsoft 2.0 and 2.5) and ProstaLund Feedback. Weighted mean differences (WMD) were calculated with a 95% confidence interval (CI) for the between-treatment differences in pooled means. The review found that TUMT was somewhat less effective than transurethral resection of the prostate (TURP) in reducing LUTS. The pooled mean symptom score for men undergoing TUMT decreased by 65% in 12 months compared to 77% in men undergoing TURP, which is a WMD of -1.83 in favour of TURP. TURP achieved a greater improvement in O\(_{\text{max}}\) (119%) than TUMT (70%), with a WMD of 5.44 mL/s in favour of TURP (3).

Similarly, a pooled analysis of three studies (two RCTs and one open label) of ProstaLund Feedback TUMT (PLFT) with 12-month follow-up showed that the responder rate was 85.3% in the PLFT group and 85.9% in the TURP group (4). In addition, pooled IPSS data indicated that a subjective, non-inferior improvement with PLFT compared to TURP (4). However, one-sided 95% CI analysis showed that the non-inferiority of PLFT compared to TURP did not reach the predetermined level, even though both PLFT and TURP appeared to improve O\(_{\text{max}}\) significantly.

Previously, urinary retention was considered to be a contraindication for TUMT. Nowadays, level 2b evidence studies have reported an 80-93% success rate for TUMT, defined as the percentage of patients who regained their ability to void spontaneously (5-7). However, these studies had a short follow-up (≤12 months), which makes it difficult to estimate the durability of TUMT outcome in patients with retention. In a study with a longer follow-up of up to 5 years, treatment failure was 37.8% in the retention group, with a cumulative risk of 58.8% at 5 years (8). One RCT compared TUMT with the α\(_1\)-blocker, terazosin (9). After 18 months' follow-up, treatment failure in the terazosin-treated patients (41%) was significantly greater than in TUMT patients (5.9%), with TUMT also achieving a greater improvement in IPSS and O\(_{\text{max}}\) (10).

5.3.3.2  Durability

Low-energy TUMT has disappointing results for durability. Several studies have reported a re-treatment rate after low-energy TUMT as high as 84.4% after 5 years (11-14), while other studies have reported re-treatment rates of 19.8-29.3% after high-energy TUMT, though with a lower mean follow-up of 30-60 months (15-18). The re-treatment rate due to treatment failure has also been estimated by a systematic review of randomised TUMT trials (3). The trials had different follow-up periods and the re-treatment rate was expressed as the number of events per person per year of follow-up. The re-treatment rate was 0.075/person years for patients treated by TUMT and 0.010/person years for TURP.

However, a prospective, randomised, multicentre study after 5 years has obtained comparable clinical results with TUMT to those seen with TRUP. The study compared TUMT (PLFT; the Core-Therm device) and TURP (19). No statistically significant differences were found in O\(_{\text{max}}\) and IPSS between the two treatment groups at 5 years. In the TUMT group, 10% needed additional treatment versus 4.3% in the TURP arm. These data suggest that, at 5 years, clinical results obtained with PLFT-TUMT were comparable to those seen after TURP. It should be noted that most durability studies have a high attrition rate; in this study, less than half of the initial group of patients treated were analysed at 4-5 years. In addition, patients who remained in the study were likely to represent the best data (responders).

5.3.4  Tolerability and safety

Treatment is well tolerated, even though most patients experience perineal discomfort and urinary urgency and require pain medication prior to or during therapy. Pooled morbidity data of randomised studies comparing TUMT and TURP have been published (3,4,20). Catheterisation time, incidence of dysuria/urgency and urinary retention were significantly less with TURP, while the incidence of hospitalisation, haematuria, clot retention, transfusions, TUR syndrome, and urethral strictures were significantly less for TUMT. In a systematic review of randomised trials (3), the re-treatment rate due to strictures during follow-up was estimated and expressed as the number of events per person per year of follow-up. Transurethral resection of the prostate patients (5.85/100 person years) were more likely than TUMT patients (0.63/100 person years) to require surgical re-treatment for strictures (meatal, urethral, or bladder neck). Pooled data showed that TUMT had less impact.
on sexual function (ED, retrograde ejaculation) than TURP (3,4,20).

5.3.5 **Practical considerations**
Endoscopy is essential because it is important to identify the presence of an isolated enlarged middle lobe or an insufficient length of the prostatic urethra. Reported low morbidity and the absence of any need for anaesthesia (spinal or general) make TUMT a true outpatient procedure, providing an excellent option for older patients with co-morbidities at high operative risk and, therefore, unsuitable for invasive treatment (21). Independent baseline parameters predicting an unfavourable outcome include advanced age of the patient, small prostate volume, mild-to-moderate BOO and a low amount of energy delivered during treatment (22). However, it should be remembered that a predictive factor for a particular device cannot necessarily be applied to other devices.

### Table 18: Efficacy of TUMT. Absolute and relative changes compared to baseline are listed for symptoms (IPSS), maximum urinary flow rate \( (Q_{\text{max}}) \), post-void residual urine \( (PVR) \), and prostate volume \( (PVol) \)

5.3.6 **Recommendations**

| Transurethral microwave therapy achieves symptom improvement comparable to TURP, but is associated with decreased morbidity and lower flow improvements. | 1a | A |
| Durability is in favour of transurethral resection of the prostate with lower re-treatment rates compared to transurethral microwave therapy | 1a | A |

\(TURP = \text{transurethral resection of the prostate}\)
5.3.7 References

5.4 Transurethral Needle Ablation (TUNA™) of the prostate

5.4.1 Mechanism of action
The TUNA™ procedure works by inducing a coagulative necrosis within the transition zone of the prostate. As a result of scar maturation, there may be a reduction in transition zone volume and, therefore, a reduction of BPO. There may also be a poorly understood neuromodulatory effect.

5.4.2 Operative procedure
The TUNA™ device delivers low-level radiofrequency energy to the prostate via needles inserted transurethrally into the prostatic parenchyma. The needles are insulated, except at their tips, so that energy is only delivered into the prostatic parenchyma and not to the urethra. Needles are placed under direct vision using an attachment to the standard cystoscope. TUNA™ is carried out under anaesthetic (local or general) or sedation.

5.4.3 Efficacy
Several, non-randomised, clinical trials have documented the clinical efficacy of TUNA™ with a fairly consistent outcome (3-7). Symptomatic improvement has ranged from 40-70%. Improvements in Qmax vary widely from 26-121% in non-retention patients. A recent report with 5 years’ follow-up in 188 patients demonstrated symptomatic improvement in 58% and improved flow in 41%. However, 21.2% of patients required additional treatment (8).

5.4.3.1 Randomised clinical trials
TUNA™ has been compared with TURP in randomised studies (8-11) with varying follow-up. The studies found both TUNA™ and TURP produced symptomatic improvement. However, TURP produced greater symptom improvement and a better QoL than TUNA™, as well as a significant improvement in Qmax after TUNA™ (Table 19). More detailed comparisons between TUNA™ and TURP can be found in some very high-quality and comprehensive, systematic reviews and meta-analyses (12,13).

5.4.3.2 Impact on bladder outlet obstruction
Seven clinical studies on the impact of TUNA™ on BPO (14,15) have demonstrated a statistically significant decrease in maximum detrusor pressure or detrusor pressure at Qmax, even though a number of patients were still obstructed following TUNA™ therapy.
There is no convincing evidence that prostate size is significantly reduced following TUNA™ (6).

Recent reports have suggested that gadolinium-enhanced MRI can be used to assess TUNA™-related treatment effects (16).

5.4.3.3 Durability
Because most studies have been short-to-medium term, concerns have been risen about the durability of effects. Even short term (12 months), up to 20% of patients treated with TUNA™ need to be re-treated with TURP (1). A recent French report described a failure rate (incorporating re-treatment) of up to 50% over a 20-month period (17).

5.4.4 Tolerability and safety
TUNA™ is usually performed as an outpatient procedure under local anaesthesia, although intravenous sedation is sometimes required (1). Postoperative urinary retention is seen in 13.3-41.6% of patients and lasts for a mean of 1-3 days; within 1 week, 90-95% of patients are catheter-free (1). Irritative voiding symptoms up to 4-6 weeks are common (2). Continence status is not affected.

5.4.5 Practical considerations
Few selection criteria have been identified. However, TUNA™ is unsuitable for patients with prostate volumes > 75 mL or isolated bladder neck obstruction. Because TUNA™ cannot treat median lobes effectively it is not clear whether men with significant median lobes will experience the benefit in published studies. There is anecdotal evidence for TUNA™ in men receiving aspirin and anti-coagulants. TUNA™ can be performed as a day-case procedure and is associated with fewer side-effects compared to TURP (e.g. bleeding, ED, urinary incontinence). However, there remain concerns about the durability of the effects achieved by TUNA™.

5.5 Laser treatments of the prostate

5.5.1 Holmium Laser Enucleation (HoLEP) and Holmium Laser Resection of the Prostate (HoLRP)

5.5.1.1 Mechanism of action

The holmium:yttrium-aluminum-garnet (Ho:YAG) laser (2140 nm) is a pulsed, solid-state laser that has been used in urology for a variety of endourological applications in soft tissues and for the disintegration of urinary calculi (1). The wavelength of the Ho:YAG laser is strongly absorbed by water. This means that the area of tissue coagulation and the resulting tissue necrosis is limited to 3-4 mm, which is enough to obtain adequate haemostasis (2). Peak power produces intense, non-thermal, localised, tissue destruction, resulting in precise and efficient cutting of prostatic tissue. Resection is usually performed when the prostate is smaller than 60 mL, while enucleation is used for larger glands.

5.5.1.2 Operative procedure

Instrumentation for this technique includes a 550 µm, end-firing, quartz fibre and an 80 W Ho:YAG laser. A continuous-flow resectoscope is required with a working element, while physiological saline solution is used as an irrigant. The basic principle of the HoLRP technique is retrograde resection of the prostate and fragmentation of resected tissue inside the bladder to allow its evacuation through the operating channel of the resectoscope (2,3). The introduction of holmium laser enucleation (HoLEP) has been a significant improvement. Mimicking open prostatectomy, the prostatic lobes are completely enucleated and pushed into the bladder, before being fragmented and aspirated afterwards by a morcellator (8).

5.5.1.3 Efficacy

Gilling et al. (4) has presented the results of a prospective RCT comparing TURP with HoLRP. To date, 120 patients have been enrolled with urodynamically-confirmed BPO (Schäfer grade > 2) and prostate sizes < 100 mL (Table 20). Preliminary analysis has revealed a significantly longer mean resection time (42.1 vs. 25.8 minutes) for HoLRP patients, while symptomatic and urodynamic improvement were equivalent in both treatment groups. In 2004, long-term results with a minimum follow-up of 4 years were published (7), which showed that there was no difference in urodynamic parameters between HoLRP and TURP after 48 months.

Gilling et al. (9) reported long-term data with a mean follow-up of 6.1 years, indicating that HoLEP results were durable and most patients remained satisfied with their procedure. Two meta-analyses, which analysed available RCTs comparing HoLEP and TURP (10,11), reported a significantly longer operation time with HoLEP (Table 20). Symptom improvements were comparable, but Q\text{max} at 12 months was significantly better with HoLEP (11). In prostates > 100 mL, HoLEP proved to be as effective as open prostatectomy for improving micturition, with equally low re-operation rates at 5-years’ follow-up (12).

5.5.1.4 Tolerability and safety

No major intra-operative complications have been described; however, the technique is a surgical procedure that requires relevant endoscopic skills. There are no specific limitations to the procedure. Patients taking anticoagulant medication and those with urinary retention can be treated safely (6). Dysuria was the most common peri-operative complication with an incidence of approximately 10% (2,4,5). Compared to TURP, HoLRP has a significantly shorter catheterisation time (20.0 vs. 37.2 hours), shorter hospitalisation time (26.4 vs. 47.4 hours) (4), and peri-operative morbidity (7). Potency, continence, symptom scores and major morbidity at 48 months were identical between HoLRP and TURP (7). Retrograde ejaculation occurred in 75-80% of patients; no postoperative impotence has been reported (2). Both meta-analyses found that HoLEP resulted in a significantly shorter catheterisation time and hospital stay, reduced blood loss and fewer blood transfusions, but had a longer operation time than TURP (10,11).

5.5.2 532 nm (‘Greenlight’) laser vaporisation of prostate

5.5.2.1 Mechanism of action

Vaporisation of prostatic tissue is achieved by a sudden increase in tissue temperature from 50°C to 100°C following the application of laser energy. A rapid increase in tissue temperature results in intracellular vacuoles (bubbles), followed by an increase in intracellular cell pressure. Once the cell pressure exceeds that compatible with cellular integrity, the vacuoles are released, as can be seen during the procedure. Because of the way in which tissue interacts with oxyhaemoglobin, laser vaporisation is increased within a wavelength range from 500-580 nm. Because of the green light emitted (λ=532 nm), this laser procedure is known as ‘Greenlight’ laser vaporisation.

It is important to include the wavelength or crystal used to produce the laser energy when describing the type of laser vaporisation used. This is because tissue interaction caused by laser energy varies according to the wavelength, applied energy, fibre architecture and tissue properties. This also means that the clinical results of different wavelengths are not comparable.
Table 20: Postoperative results of holmium resection (HoLRP) or enucleation (HoLEP) vs. transurethral resection of the prostate (TURP) open prostatectomy (OP) and ‘Greenlight’ laser vaporisation (KTP) vs. TURP. Absolute and relative changes compared to baseline, with regard to symptoms (AUA-SI/IPSS), maximum urinary flow rate ($Q_{\text{max}}$), post-void residual urine (PVR), and prostate volume.

5.5.2.2  Operative procedure
Laser vaporisation of the prostate using an 80 W, 532 nm laser is performed by using a 600 µm side-firing laser fibre with a 70°-deflecting laser beam and a 30°-deflecting laser cystoscope. Cold sterile saline or water can be used for irrigation during the procedure. Under direct vision, vaporisation is performed with a fibre-sweeping technique, usually starting at the bladder neck and continuing with the lateral lobes and the apex (13). The visible, side-fired, laser beam leads to an immediate and apparent tissue ablation.

5.5.2.3  Efficacy
Numerous studies, predominantly with 80 W lasers, have been published in recent years (Table 20). The lack of long-term data means it is not yet possible to make final conclusions about the duration of improvement. A significant improvement in symptoms and voiding parameters and a re-operation rate comparable to TURP was reported in a 5-year follow-up study of 500 patients (14). Despite ongoing oral anticoagulation in 45% of the patients (n = 225), no severe intra-operative complications were observed. The mean catheterisation and post-operative hospitalisation time was 1.8 (0-10) and 3.7 (0-35) days, respectively.

Three years after photolaser vaporisation in men with mean vapourised prostate volumes of 28 ± 42 mL, the mean IPSS was 8.0, QoL score was 1.3, and Q_{max} was 18.4 mL/s. The re-treatment rate was 6.8%. Urethral and bladder neck strictures were observed in 4.4% and 3.6% of patients, respectively. However, follow-up was available only in a few patients. Significant improvements in voiding parameters at a follow-up of 12 months were demonstrated with urodynamic investigation (15). At 12 months' follow-up, the mean urethral opening pressure (Pdetopen; 76.2 vs. 37.4 cm H_{2}O) and detrusor pressure at Q_{max} (Pdetmax; 75 vs. 36.6 cm H_{2}O) were significantly reduced compared to baseline. The Q_{max} improved by 113% (mean 18.6 mL/s) compared to pre-operative Q_{max} (mean 7.9 mL/s).

To date, only two prospective RCTs and three non-randomised trials have been published. The longest available follow-up of an RCT is only 12 months; this trial indicated that 532 nm laser vapourisation was equivalent to TURP in symptom improvement (20). Both groups showed a significant increase in Q_{max} from baseline. In the TURP group, flow increased from 8.7 to 17.9 mL/s (149%) and in the laser vaporisation group from 8.5 to 20.6 mL/s (167%). The IPSS decreased from 25.4 to 12.4 (50%) in the TURP group and from 26 to 12 (50%) in the laser vaporisation group. Laser vaporisation also resulted in significant decreases (averaging 119 mL pre-operatively in the TURP group and 147 mL in the laser vaporisation group), with reductions to 37 and 27 mL, respectively. Similar trends were seen concerning bother and quality of life scores.

5.5.2.4  Tolerability and safety
Safety was shown in various, prospective, non-randomised trials in patients with oral anticoagulation, urinary retention, or prostates > 80 mL (16-19). Regarding intra-operative safety, 532 nm laser vapourisation was reported to be superior to TURP in non-randomised trials (21,22). It is also an effective technique when compared to TURP, producing equivalent improvements in flow rates and IPSS with the advantages of markedly reduced length of hospital stay, duration of catheterisation, and adverse events in a randomised trial. The duration of catheterisation was significantly less in the laser vapourisation than the TURP group, with a mean (range) of 13 (0–24) hours vs. 44.7 (6–192) hours. Additionally, the length of hospital stay was significantly shorter with laser vapourisation, with a mean (range) of 1.09 (1-2) and 3.6 (3-9) days in the laser vapourisation and TURP groups, respectively (23).

5.5.2.5  Practical considerations
Despite the efficacy of TURP in terms of tissue removal and reduction of BPO, a higher rate of peri-operative complications has resulted in an ongoing search for less invasive and safer surgical techniques. Based on the wavelength and power, laser can be used either for coagulation, vaporisation, or cutting (‘enucleation’). Non-thermal effects, also known as ‘ablation’, also result in tissue destruction. Functional results will therefore differ in terms of peri-operative handling of different laser devices, including learning curve, debulking issue, durability of results, and type of complications. The treatment choice how to reduce BPO is dependent on the availability of the armamentarium, patient’s choice, concomitant morbidity or drug use, and experience of the surgeon.

Several types of new generation lasers for prostate surgery have emerged during the last decade, including the holmium:YAG, potassium titanyl phosphate:yttrium aluminium garnet (KTP:YAG), thulium:yttrium aluminium garnet (thulium:YAG), light blue optics:yttrium aluminium garnet (LBO:YAG) and the diode lasers. Energy can be transmitted through a bare, right-angle or interstitial fibre. Each laser has wavelength-specified energy–tissue interaction. Prostatic tissue destruction results from both thermal and non-thermal effects. In 2009, published data were only available for HoLEP, 80 W Greenlight PV (photoselective vapourisation), and thulium:YAG laser prostatectomy. Only a few articles have been published on thulium:YAG prostatectomy, which may be used as a vapourising, coagulating, or cutting laser. The lack of published data means that firm conclusions are not yet possible with regard to the different laser treatments.

Prostate stents

5.6.1 Mechanism of action

The use of an endoprosthesis to preserve luminal patency is a well-established concept, while in 1980 Fabian first describing stenting of the prostatic urethra to relieve BPO (1). Prostatic stents were primarily designed as an alternative to an indwelling catheter in patients unfit for surgery because of co-morbidity. However, prostatic stents have also been assessed by several studies as a primary treatment option in patients without significant co-morbidities (2,3).

A prostatic stent requires a functioning detrusor, so that the bladder still has the ability to empty itself. This is in contrast to an indwelling catheter, which drains the bladder passively (4). Stents can be temporary or permanent. Permanent stents are biocompatible, allowing epithelialisation, so that eventually they become embedded in the urethra. Temporary stents do not epithelialise and may be either biostable or biodegradable. Temporary stents can provide short-term relief from BPO in patients temporarily unfit for surgery or after minimally invasive treatment (MIT) (4).

5.6.2 Operative procedure

Stent insertion is mostly performed in an outpatient setting under local anaesthesia. Prior to stent insertion, the length of the prostatic urethra is measured to determine the stent length. After the patient has been placed in the lithotomy position, the stent is advanced through the urethra until the tip of the prostatic urethral segment is positioned in the bladder. It is important that the stent is not positioned inside the external urethral sphincter as it may cause stress urinary incontinence. To confirm proper positioning, abdominal ultrasound or cystoscopy is performed. Removal of a temporary stent is achieved by pulling the retrieval suture, until the stent is completely retracted, or by using graspers under endoscopic guidance. It can be difficult to remove permanent stents in cases of stent migration, stent encrustation or epithelial in-growth, and general anaesthesia is usually needed. In general, antibiotic prophylaxis is not necessary unless there has been a positive urine culture.
5.6.3  Efficacy
There have been several small case studies on a range of stents of different designs and materials, which have provided a low level of evidence for their use. Table 21 describes the most important studies (2,5-9). All studies during follow-up have observed a significant attrition rate. There is only one RCT that has compared two versions of a blind-placement prostatic stent (BPS) for BPO (10), and there have been no studies comparing stents with sham or other treatment modalities. The BPS system is a temporary stent consisting of a soft silicone stent, retrieval line, and delivery device, with the difference between BPS-1 and BPS-2 being an additional 2-cm bulbular segment. This bulbular segment results in a significantly lower migration rate with BPS-2 (5%) compared with BPS-1 (85%), but the bulbular segment also caused significant discomfort (10). BPS-2 also has better symptom scores and voiding function than BPS-1, but only Q\text{max} reached statistical significance. The results from this study appear to indicate that stent design has a critical role in the efficacy and safety of prostatic stents (10).

5.6.3.1 Permanent stents (UroLume endourethral prosthesis)
The main representative of the permanent stents is the UroLume endourethral prosthesis. A recent systematic review identified 20 case series, with a total of 990 patients who received the UroLume stent (11). The 10 studies that reported symptom scores demonstrated improved symptoms following stent insertion, although the timing of assessment varied between studies. The reported decrease in Madsen-Iversen scores ranged from 7.9 to 14.3 points, while the IPSS decreased by 10-12.4 points (11). Additionally, the mean Q\text{max} increased between 4.2 and 13.1 mL/s following stent insertion. The pooled data from studies with patients using permanent transurethral catheters showed that 84% of patients (148/176) regained the ability to void spontaneously after UroLume treatment, with the mean Q\text{max} ranging from 8.8 to 20 mL/s. At 12 years of follow-up, the mean IPSS, Q\text{max}, and PVR were 10.82, 11.5 mL/s and 80 mL, respectively (12).

5.6.3.2 Non-epitheliasing (temporary) prostatic stent (Memokath)
The best data on non-epitheliasing prostatic stent are provided by a systematic review of the efficacy of Memokath, a self-expanding metallic prostatic stent (13). In total, 14 case series with 839 patients were reviewed. Analysis of the seven studies reporting symptom scores found that Memokath insertion was associated with a reduction of 11-19 points in the IPSS and a reduction of 9 points in the Madsen-Iversen score. However, it is important to note that the assessment was made at different times after stent placement. Similarly, stent insertion resulted in a Q\text{max} increase of 3 to 11 mL/s, although again the time of assessment was variable after placement (13).

5.6.4 Tolerability and safety
In general, stents are subject to misplacement, migration, poor tolerability because of exacerbation of LUTS, and encrustation (4). The main adverse events immediately following stent placement include perineal pain or irritative voiding symptoms in most patients.

The systematic review of the UroLume reported a 16% failure rate (104/666) within 12 months of insertion, mainly due to stent misplacement or migration (37%) or recurrent obstructive or irritative voiding symptoms (14%). The overall failure rate at 5 years was 27% (50/188 stents), although many patients were lost to follow-up or died with the stent in situ (11). In the study with the longest follow-up, 18% of the patient population (11 men) completed 12 years of follow-up with the Urolume stent in situ, whereas 29 stents were removed (failure rate, 47%) and 22 patients (34%) died of diseases non related to male LUTS.

5.6.5 Practical considerations
In search for the ideal prostatic stent, a range of different stent types has been developed and undergone clinical study. Because of the side effects and high migration rate, prostatic stents have a limited role in the treatment of BPO. Prostatic stents remain an alternative to transurethral catheterisation for men who have (recurrent) urinary retention and are at high risk for surgery.

5.7 Emerging operations

5.7.1 Intra-prostatic ethanol injections

5.7.1.1 Mechanism of action
Absolute (dehydrated, 95-98%) ethanol is injected into the prostatic parenchyma for the treatment of LUTS secondary to BPO. The precise mechanism of action in both humans and animals remains unclear. The use of ethanol was investigated in the canine model and demonstrated the ability of ethanol to cause inflammation, coagulative necrosis with protein denaturation and cell membrane lysis, and, finally, atrophy and ablation of prostatic tissue resulting in cavity formation (1-4). Tissue necrosis was typically wedge-shaped (4). The volume of injected ethanol correlated only moderately with the size of tissue necrosis (4). Intra-prostatic cavity formation appeared in the canine model after 7 days (3).

5.7.1.2 Operative procedure
Liquid dehydrated ethanol or ethanol gel is injected into the prostatic parenchyma with a 20-22 gauge needle either transurethrally, transperineally, or transrectally. The transurethral approach (TEAP or TUEIP) has been used more frequently (5-14) than the transperineal (11,15,16) or transrectal approaches (11).

Specific devices have been developed for the transurethral delivery of ethanol (InecTx™ in the USA and Prostaject™ in Europe) (17). There is no consensus on the number of injection sites or injection volumes, which depend on total prostate volume, urethral length and/or presence of a prostate median lobe, and have ranged from 2 mL to 25 mL of ethanol per patient in different studies (with the injection volume being up to 42% of the volume of the prostate).

Local anaesthesia supplemented by conscious sedation may be considered, although regional or general anaesthesia were chosen by most patients. The procedure is usually completed within approximately 30 minutes. The majority of patients need an indwelling catheter after the procedure.

5.7.1.3 Efficacy
So far, 12 trials (5-16) have been published (Table 22), with the majority having investigated men refractory to medical treatment. Only one trial investigated patients with urinary retention (10). None of these trials was randomised against TURP or other minimally invasive procedures for BPH-LUTS or BPO. Mean follow-up varied among studies from 12 to 208 weeks (3-48 months).

The majority of trials demonstrated a significant reduction in symptoms (IPSS -41% to -71%) and PVR (-6% to -99%) as well as a significant improvement in the maximum urinary flow rate ($Q_{\text{max}} +35\%$ to $+155\%$) and QoL (IPSS-QoL -47% to -60%). Prostate volume decreased significantly in approximately half the trials (-4% to -45%). After an initial strong reduction in prostate volume, 1-2 years postoperatively prostate size increased again, although LUTS and peak urinary flow remained significantly improved (8). No predictive efficacy parameter or dose-response relationship has been found (8,12).

Several trials demonstrated a considerable number of retreatments within the first year after the procedure (usually treated by a second ethanol injection, TURP, or open prostatectomy). Little is known about the durability of clinical effects later than 1 year after the operation; one trial with a mean follow-up of 3 years showed a retreatment rate of 41% (8).

Absolute and relative changes compared with baseline are listed with regard to symptoms (IPSS), maximum urinary flow rate (Qmax), post-void residual (PVR), and prostate volume. a = significant compared with baseline (indexed whenever evaluated); † = patients with urinary retention; * = three study arms comparing transurethral, transrectal and transperineal injections.

5.7.1.4 Tolerability and safety

Frequently reported adverse events included:
- perineal or abdominal discomfort/pain;
- bladder storage symptoms (< 40%);
- haematuria (< 40%);
- UTI or epididymitis;
- urinary retention.

Less frequently reported (< 5%) adverse events included:
- decreased libido;
- retrograde ejaculation;
- urge urinary incontinence;
- urethral stenosis;
- ED.

Animal studies revealed a high percentage of urethral sphincter damage and stress urinary incontinence when ethanol was injected via the perineal route (1), but these complications have not been reported in humans (15,16). One man developed a big bladder stone six months after treatment, most probably due to calcification of sloshed necrotic prostatic masses (18). Two cases of severe complications after ethanol injections have been reported; bladder necrosis required cystectomy and urinary diversion (9).
5.7.1.5 **Practical considerations**

Intra-prostatic ethanol injections are considered to be a minimally invasive treatment option for patients with LUTS secondary to BPO. However, the mechanism of action, patient selection and application of ethanol (the number of injection sites and the injection volume) have not been well investigated, severe adverse events occurred in some patients, and long-term results are sparse. Intra-prostatic ethanol injections are therefore still regarded as experimental and should be used only in trials.

Randomised-controlled trials with long-term follow-up comparing ethanol injections with TURP, other minimally invasive procedures, or drugs are needed to be able to judge adequately the value of this treatment modality.

5.7.1.6 **Recommendations**

5.7.2 Intra-prostatic botulinum toxin injections

5.7.2.1 Mechanism of action
BTX is the exotoxin of the bacterium Clostridium botulinum. This 150 kDa toxin is the most potent neurotoxin known in humans, and causes botulism (food-borne, wound or infant). Seven subtypes of BTX are known (types A-G), of which subtypes A and B have been manufactured for use in humans.

Experience with intra-prostatic injections for the treatment of LUTS/BPO exists only for BTX-A. The precise mechanism of action has been evaluated in experimental animals but is not fully understood. BTX-A blocks the release of neurotransmitters (e.g. acetylcholine or norepinephrine) from pre-synaptic nerves (1). BTX-A directly or indirectly reduces LUTS by induction of apoptoses of prostatic (epithelial) cells leading to tissue atrophy and prostate size reduction (2-4), inhibition of sensory neurons in the prostate and reduction of afferent signals to the central nervous system (3), and/or relaxation of smooth muscle cells in the prostatic parenchyma and reduction of BPO (4-6). Down-regulation of 1A adrenergic receptors in the prostate may contribute to smooth muscle cell relaxation (3). The latter two mechanisms are summarised as chemical denervation that possibly has a negative influence on prostate growth.

5.7.2.2 Operative procedure
Under ultrasound visualisation, BTX-A can be injected into the prostatic parenchyma transperineally, transurethrally or transrectally, using a 21-23 gauge needle. The transperineal approach has been described most frequently (7-13); the transurethral (5) and transrectal routes (14,15) have also been used but applied less often. Botox™ (Allergan, Irving, CA, USA) was employed in all but one study (13).

Different therapeutic doses (100-300 units Botox™ or 300-600 units Dysport™) and dilutions (25-50 units Botox™/mL or 75 units Dysport™/mL) were used in various studies, but doses and dilutions have not been systematically tested. Doses of 100 units Botox™ have been suggested for prostate sizes < 30 mL, 200 units for sizes between 30 mL and 60 mL, and 300 units for sizes > 60 mL (9). For Dysport™, 300 units were used for prostate sizes < 30 mL, and 600 units for sizes > 30 mL were used (13). The majority of patients were treated without anaesthesia, local anaesthesia, or sedation.

5.7.2.3 Efficacy
So far, 11 trials have been published (Table 23 investigating intra-prostatic BTX-A injections in patients with BPH/LUTS who required or were resistant to medical therapy, or patients with an indwelling urethral catheter due to acute or chronic urinary retention (5,14,15). Only two trials were randomised, one against injection of saline solution (7), the other against α1-blocker therapy (12).

The majority of patients in the published trials received only a single injection of BTX-A and mean follow-up ranged between 12 and 120 weeks (3 to 30 months). All trials reported significant improvements with regard to symptoms (IPSS -39% to -79%) and urinary flow rate ($Q_{\text{max}} +27\%$ to $+122\%$), or a decrease of prostate volume (-11% to -61%). Post-void residual urine decreased in all studies, but reduction was significant in only approximately half of the trials. BTX-A injection therapy was significantly superior to saline injection in the randomised-controlled trial with regard to symptom and $Q_{\text{max}}$ improvement as well as PVR and prostate volume reduction; all parameters were significantly different compared with baseline or saline solution within the first treatment month (7).
In patients with urinary retention before BTX-A injections, 80-100% of men could void spontaneously within one month of the operation, and maintained voiding throughout the follow-up period. Little is known about the long-term effects and durability of the treatment; prostate volume seems to increase again after 6-12 months (11,14) despite stable improvements in symptoms, $Q_{\text{max}}$ and PVR. Retreatment rates with BTX-A were as high as 29% (11).

Absolute and relative changes compared with baseline are listed with regard to symptoms (IPSS), maximum urinary flow rate ($Q_{\text{max}}$), post-void residual (PVR), and prostate volume. a = significant compared with baseline (indexed whenever evaluated); b = significant compared with placebo (saline solution) or $\alpha$1-blockers; † = patients with acute or chronic urinary retention; * = Botox™; ‡ = Dysport™

5.7.2.4 Tolerability and safety
BTX-A injections were well tolerated in all studies, and no systemic adverse events have yet been reported to have arisen from BTX-A. There was no need for postoperative analgesia. Adverse events were dysuria in ≤ 19%, haematuria in ≤ 14%, and acute prostatitis in one patient (2%). Urinary retention occurred in ≤ 6%, but many patients received a transurethral catheter or performed clean intermittent catheterisation during the early postoperative period (one week to one month) (8,14).

5.7.2.5 Practical considerations
BTX-A injections into the prostatic parenchyma seem to be a promising and quick minimally invasive treatment modality with low morbidity for patients who are refractory to medical treatment or in urinary retention. However, despite the excellent and homogeneous outcomes in published trials, BTX-A has been injected into only a few patients, and all trials have a limited follow-up. Only two randomised-controlled trials have been published so far. Trials with a larger number of patients, randomisation against saline injections, drugs, TURP, or other minimally invasive treatments, and long-term follow-up are therefore necessary to judge adequately the value of intra-prostatic BTX-A injections in the context of other available medical or surgical treatments of LUTS/BPO.

5.8 Summary treatment

The choice of treatment depends on:
- findings assessed during evaluation;
- treatment preferences of the individual patient;
- ability of the treatment modality to change assessed findings;
- expectations to be met in terms of speed of onset, efficacy, side-effects, quality of life, and disease progression.

Table 24 provides differential information about conservative, medical and surgical treatment options described in the EAU Guidelines on Male LUTS, including BPO. Note that treatment modalities may be combined leading to different effects.

Table 24: Speed of onset and influence on basic parameters with conservative or surgical treatment modalities for the management of non-neurogenic male LUTS. Note that the drug treatment studies have typically used data after a run-in phase as baseline, whereas those of interventional treatments did not.

LUTS = Lower Urinary Tract Symptoms; $Q_{max}$ = maximum urinary flow rate; PVR = post-void residual urine
Key to Table:
- no influence
+ mild influence
++ moderate influence
+++ strong influence
++++ very strong influence
? unknown

Behavioural with or without medical treatments are usually the first choice of therapy. A flowchart illustrating conservative and medical treatment choices according to evidence-based medicine and patients’ profiles is provided in Figure 3.

Figure 3: Treatment algorithm of male lower urinary tract symptoms (LUTS) using medical and/or conservative treatment options. Treatment decisions depend on results assessed during initial evaluation (◊). Minus (−) indicate the absence and plus (+) the presence of the condition.

Surgical treatment is usually required when patients have experienced recurrent or refractory urinary retention, overflow incontinence, recurrent UTIs, bladder stones or diverticula, treatment-resistant macroscopic haematuria due to BPH/BPE, or dilatation of the upper urinary tract due to BPO, with or without renal insufficiency (absolute operation indications, need for surgery). Additionally, surgery is usually needed when patients have had insufficient relief in LUTS or PVR after conservative or medical treatments (relative operation indications). The choice of the surgical technique depends primarily on prostate size, co-morbidities of the patient, and the ability to have anaesthesia but also on patients’ preferences, willingness to accept surgery-associated side effects, availability of the surgical armamentarium, and experience of the surgeon with these operation techniques. A flowchart illustrating surgical treatment choices according to evidence-based medicine and patients’ profiles is provided in Figure 4.
6. FOLLOW-UP

6.1 Watchful waiting – behavioural
Patients who elect to pursue a WW policy should be reviewed at 6 months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits:

- I-PSS
- Uroflowmetry and PVR urine volume.

6.2 Medical treatment
Patients receiving α-blockers, muscarinic receptor antagonists, or the combination of α-blockers with 5α-reductase inhibitors or muscarinic receptor antagonists should be reviewed 4 to 6 weeks after drug initiation in order to determine treatment response. If patients gain symptomatic relief in the absence of troublesome adverse events, drug therapy may be continued.

Patients should be reviewed at 6 months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following tests are recommended at follow-up visits:
Patients receiving 5α-reductase inhibitors should be reviewed after 12 weeks and 6 months to determine their response and adverse events. Follow-up visits are similar to the above mentioned drugs. The following are recommended at follow-up visits:

- I-PSS;
- Uroflowmetry and PVR urine volume.

Patients receiving desmopressin, serum sodium concentration should be measured at day 3 and 7 as well as after 1 month and, if serum sodium concentration has remained normal, every 3 months subsequently. The following tests are recommended at follow-up visits:

- Serum-sodium concentration;
- Frequency-volume chart.

After dose adjustment, follow-up should be repeated likewise.

6.3 Surgical treatment

Patients after prostate surgery should be reviewed 4 to 6 weeks after catheter removal in order to evaluate treatment response and adverse events. If patients have symptomatic relief and are without adverse events no further re-assessment is necessary. The following tests are recommended at follow-up visit after 4 to 6 weeks:

- I-PSS;
- Uroflowmetry and PVR urine volume.

7. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

AVP     arginine vasopressin
BOO     bladder outlet obstruction
BOO(I)  bladder outlet obstruction (index)
BPE     benign prostatic enlargement
BPH     benign prostatic hyperplasia
BPO     benign prostatic obstruction
cGMP    cyclic guanosine monophosphate
CombAT  combination of avodart® and tamsulosin
DHT     dihydrotestosterone
EBM     evidence-based medicine
ED      erectile dysfunction
eNOS    endothelial
ER      extended release
GITS    gastrointestinal therapeutic system
IFIS    intra-operative floppy iris syndrome
IPSS    international prostate symptom score
IR      immediate release
LUTS    lower urinary tract symptoms
MR      modified release
MTOPS   medical therapy of prostatic symptoms
NAION   non-arteritic anterior ischemic optic neuropathy
NO      Nitric oxide
NOS     NO synthases
nNOS    neuronal
n.s.    not significant
OCAS    oral controlled absorption system
PDE     phosphodiesterase
PSA     prostate specific antigen
PVR     post-void residual
Qmax    maximum urinary flow rate during free uroflowmetry
QoL     quality of life
RR      relative risk
SHBG    sexual hormone binding globulin
SR      sustained release
tmax    time to maximum plasma concentration
t½      elimination half-life
TUIP    transurethral incision of the prostate
TUMT    transurethral microwave therapy
TUNATM  transurethral needle ablation
TURP    transurethral resection of the prostate
UTI     urinary tract infection
WW      watchful waiting

Conflict of interest
All members of the Male LUTS Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

5. CONCLUSION

6. ABBREVIATIONS USED IN THE TEXT
1. BACKGROUND

1.1 Introduction
Erectile dysfunction (ED) and premature ejaculation (PE) are the two main complaints in male sexual medicine (1,2). New oral therapies have completely changed the diagnostic and therapeutic approach to ED and the Guidelines Office of the European Association of Urology (EAU) has appointed an Expert Panel to update previously published EAU guidelines for ED or impotence (3,4).

1.2 Methodology
The update is based on a systemic literature search performed by the panel members. The MedLine database was searched using the major Medical Subject Headings (MeSH) terms “erectile dysfunction”, “sexual dysfunction” “ejaculation”. MedLine search was supplemented by the term “premature ejaculation” in all search fields. All articles published between January 2009 (previous update) and January 2013 were considered for review. The Expert Panel has also identified critical problems and knowledge gaps, setting priorities for future clinical research.

1.3 Level of evidence and grade of recommendation
References in the text have been assessed according to their level of scientific evidence (LE), and guideline recommendations have been graded follow the listings in Tables 1 and 2, based on the Oxford Centre for Evidence-based Medicine Levels of Evidence (5). Grading aims to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

</table>

*Modified from (5).

It should be noted that when recommendations are graded, the link between the LE and grade of recommendation (GR) is not directly linear. Availability of RCTs may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results. Alternatively, absence of high level of evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. There may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful. Whenever this occurs, it is indicated in the text as “upgraded based on panel consensus”. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences, and costs when a grade is assigned (4-6).

The EAU Guidelines Office does not perform structured cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever these data are available, the expert panel will include the information.

*Modified from (5).
1.4  **Publication History**

The first European Association of Urology (EAU) Guidelines on Erectile Dysfunction were published in 2000 (6) with subsequent updates in 2001, 2002, 2004, 2005 and 2009. In particular the 2009 document presented a significant update of the previous publication with the inclusion of the topic “Premature Ejaculation” and the text was renamed to “EAU Guidelines on Male Sexual Dysfunction” (7). In 2011 the expert panel decided to develop separate guidelines addressing Penile Curvature, which resulted in a publication in 2012 (8).

Several scientific summaries have been published in the EAU scientific journal, European Urology (9-12). Quick reference documents (pocket guidelines) are available presenting the main findings of both the Male Sexual Dysfunction Guidelines and the Penile Curvature Guidelines. These documents follow the updating cycle of the underlying large texts. All material can be viewed and downloaded for personal use at the EAU website. The EAU website also includes a selection of translations and republications produced by national urological associations: [http://www.uroweb.org/guidelines/online-guidelines/](http://www.uroweb.org/guidelines/online-guidelines/).

The chapters on Erectile Dysfunction were peer-reviewed prior to publication.

1.5  **Potential conflict of interest statement**

The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU website: [http://www.uroweb.org/guidelines/online-guidelines/](http://www.uroweb.org/guidelines/online-guidelines/).

1.6  **References**

2. ERECTILE DYSFUNCTION

2.1 Epidemiology and risk factors

Erection is a neuro-vasculo-tissular phenomenon under hormonal control. It includes arterial dilatation, trabecular smooth muscle relaxation, and activation of the corporeal veno-occlusive mechanism (1,2).

Erectile dysfunction is defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance. Although ED is a benign disorder, it may affect physical and psychosocial health and may have a significant impact on the quality of life (QoL) of sufferers and their partners (3). There is increasing evidence that ED can be an early manifestation of coronary artery and peripheral vascular disease; thus, ED should not be regarded only as a QoL issue but also as a potential warning sign of cardiovascular disease (4-8).

2.1.1 Epidemiology

Epidemiological data have shown a high prevalence and incidence of ED worldwide. The first large, community-based study of ED was the Massachusetts Male Aging Study (MMAS) (3). The study reported an overall prevalence of 52% ED in non-institutionalised 40-70-year-old men in the Boston area; specific prevalence for minimal, moderate, and complete ED was 17.2%, 25.2%, and 9.6%, respectively. In the Cologne study of men aged 30-80 years, the prevalence of ED was 19.2%, with a steep age-related increase from 2.3% to 53.4% (9). In the National Health and Social Life Survey (NHSLS), the prevalence of sexual dysfunction in males (not specific ED) was 31% (10). The incidence rate of ED (new cases per 1,000 men annually) was 26 in the MMAS study (11), 65.6 (mean follow-up of 2 years) in a Brazilian study (12), and 19.2 (mean follow-up of 4.2 years) in a Dutch study (13). In Taiwan, the prevalence of ED was 27% among all patients investigated and 29% among those aged ≥ 40 years (14). In Ghana, the overall prevalence of ED is 59.6% and there are positive correlations between ED, dissatisfaction, age and other sexual dysfunctions (15). Differences between these studies can be explained by differences in methodology and in the ages, socioeconomic and cultural status of the populations studied.

Data from epidemiological studies have demonstrated consistent and compelling evidence for an association between lower urinary tract symptoms (LUTS)/benign prostatic hypertrophy (BPH) and sexual dysfunction in aging men that is independent of the effects of age, other comorbidities, and various lifestyle factors (16). The Massachusetts Male Aging (MSAM-7) study systematically investigated the relationship between LUTS and sexual dysfunction in > 12,000 men aged 50-80 years. It was performed in the US and six European countries (France, Germany, Italy, Netherlands, Spain, and UK). Eighty-three percent of men considered themselves sexually active, and 71% reported at least one episode of sexual activity in the past 4 weeks. The overall prevalence of LUTS was 90%. Only 19% of men had sought medical help for LUTS and only 11% were medically treated. The overall prevalence of ED was 49%, and 10% of patients reported complete absence of erection. The overall prevalence of ejaculation disorders was 46% and 5% reported anejaculation (17).

2.1.2 Risk factors

Erectile dysfunction shares common risk factors with cardiovascular disease (e.g., lack of exercise, obesity, smoking, hypercholesterolaemia, and metabolic syndrome); some of which can be modified. Moreover, men with mild ED have similar risk factors to those of a general ED clinical trial population. Thus, mild ED is an important indicator of risk for associated underlying disease. Men complaining of mild ED should be evaluated adequately (for underlying cardiovascular risk) (18).

In the MMAS, men who began exercising in midlife had a 70% reduced risk for ED compared to sedentary men and a significantly lower incidence over an 8-year follow-up period of regular exercise (19). A multicentre, randomised, open-label study in obese men with moderate ED compared 2 years of intensive exercise and weight loss with a control group given general information about healthy food choices and exercise (20). Significant improvements in body mass index (BMI) and physical activity scores, as well as erectile function, were observed in the lifestyle intervention group. These changes were highly correlated with both weight loss and activity levels.

Some studies have shown some evidence that lifestyle modification and pharmacotherapy for cardiovascular risk factors are effective in improving sexual function in men with ED. However, it should be emphasized that more controlled prospective studies are necessary to determine the effects of exercise or other lifestyle changes in prevention or treatment of ED (6).

2.1.3 Post-radical prostatectomy ED, post-radiotherapy ED & post-brachytherapy ED

Radical prostatectomy (RP) in any form (open, laparoscopic, or robotic) is a widely performed procedure for patients with clinically localised prostate cancer and a life expectancy of at least 10 years. This procedure may lead to treatment-specific sequelae affecting health-related QoL. This outcome has become increasingly
important with the more frequent diagnosis of prostate cancer in younger patients (21-22). Research has shown that 25-75% of men experience postoperative ED (23). A systematic review has shown that incidence of potency recovery after robotic prostatectomy is influenced by numerous factors. It reported, for the first time, a significant advantage in favor of robotic laparoscopic radical prostatectomy in comparison with retropubic radical prostatectomy in terms of 12-month potency rates (24). However, there was no significant difference between laparoscopic RP and robot-assisted laparoscopic RP. Today, we do not have enough evidence-based data to consider that robot-assisted laparoscopic RP has any advantageous effect on functional outcome. Experience of the surgeon seems to be the main factor besides preservation of neurovascular bundles and patient age.

Post-RP ED is multifactorial. Cavernosal nerve injury induces proapoptotic (loss of smooth muscle) and profibrotic (increase in collagen) factors within the corpora cavernosa. These changes may also be caused by poor oxygenation due to changes in the blood supply to the cavernosa because of possible arterial damage during the surgical procedure.

Preoperative potency is a major factor associated with the recovery of erectile function after surgery, therefore, patients being considered for nerve-sparing radical prostatectomy (NSRP) should ideally be potent preoperatively (24-29). It is also clear that cavernosal nerves must be preserved to ensure erectile function recovers after RP. In addition, the role of vascular insufficiency is of increasing interest in postoperative ED (30,31).

ED is also a common sequela after external beam radiotherapy and brachytherapy for prostate cancer. The mechanisms contributing to ED after prostate irradiation involve injury to the neurovascular bundles, penile vasculature, and cavernosal structural tissue (32,33). Alternative treatments for prostate cancer including cryotherapy and high-intensity focused ultrasound are associated with equivalent or worsened rates of ED compared to surgery or radiation therapy (34,35).

2.1.4 Managing ED: implications for everyday clinical practice

Advances in basic and clinical research in ED during the past 15 years have led to the development of a variety of new treatment options, including pharmacological agents for intracavernous, intraurethral, and oral use (36-38). Reconstructive vascular surgery is reserved for select cases of arterial insufficiency, with no current indications for venous ligation procedures, given the poor overall outcomes (39,40).

An increasing number of men are currently seeking help for ED due to the growing public awareness of the condition and the availability of effective, safe and user-friendly oral drug therapy. However, not all physicians evaluating and treating ED have appropriate background knowledge and clinical experience in sexual medicine. Thus, men with ED may receive little or no evaluation before treatment and will therefore not receive treatment for any underlying disease that may be causing their ED. Other men without ED may be requesting treatment simply to enhance their sexual performance.

2.2 Diagnostic evaluation

2.2.1 Basic work-up

The first step in evaluating ED is always a detailed medical and sexological history of patients and partners when available (1,2). Often it is not possible to include the partner on the patient’s first visit, but an effort should be made to include the partner at the second visit. The pathophysiology of ED may be vasculogenic, neurogenic, anatomical, hormonal, drug-induced and/or psychogenic (Table 3) (3). Taking a comprehensive medical history may reveal one of the many common disorders associated with ED.

It is important to establish a relaxed atmosphere during history-taking. This will make it easier to ask questions about erectile function and other aspects of sexual history. A relaxed atmosphere will also make it easier to explain the diagnosis and therapeutic approach to the patient and his partner.

2.2.1.1 Sexual history

The sexual history must include (when available) information about previous and current sexual relationships, current emotional status, onset and duration of the erectile problem, and previous consultations and treatments. The sexual health status of the partner(s) (when available) can also be useful. A detailed description should be made of the rigidity and duration of both sexually stimulated and morning erections and of problems with arousal, ejaculation, and orgasm. Validated psychometric questionnaires, such as the International Index for Erectile Function (IIEF) (4), help to assess the different sexual function domains (i.e., sexual desire, erectile function, orgasmic function, ejaculation, intercourse, and overall satisfaction), as well as the impact of a specific treatment modality. Psychometric analysis also supports the use of erectile hardness score as a simple, reliable and valid tool for the assessment of penile rigidity in practice and in clinical trials research (5).

In cases of clinical depression, the use of a 2-question scale for depression is recommended: “During the past month have you often been bothered by feeling down, depressed or hopeless? During the past month have you often been bothered by little interest or pleasure, doing things?” (6). Patients should be screened for symptoms of possible of possible hypogonadism, including decreased energy, libido, fatigue, and cognitive impairment, as well as for symptomatic lower urinary tract symptoms. Where indicated, screening questionnaires, such as the International Prostate Symptom Score may be utilised.

2.2.1.2 Physical examination

Every patient must be given a physical examination focused on the genitourinary, endocrine, vascular, and neurological systems (1). A physical examination may reveal unsuspected diagnoses, such as La Peyronie’s disease, prostatic enlargement or irregularity/nodularity, or signs and symptoms suggesting hypogonadism (small testes, alterations in secondary sexual characteristics etc.) (2). A rectal examination should be performed in every patient older than 40 years. Blood pressure and heart rate should be measured if they have not been assessed in the previous 3-6 months. Particular attention must be given to patients with cardiovascular disease (Section 2.2.2).

2.2.1.3 Laboratory testing

Laboratory testing must be tailored to the patient’s complaints and risk factors. Patients may need a fasting glucose or HbA1c and lipid profile if not recently assessed. Hormonal tests include a morning sample of total testosterone. If indicated bioavailable or calculated-free testosterone may be needed to corroborate total testosterone measurements. However, the threshold of testosterone to maintain ED is low and ED is usually a symptom of more severe cases of hypogonadism (7). For levels > 8 nmol/l the relationship between circulating testosterone and sexual function is very low (7,8).

Additional laboratory tests may be considered in selected patients, for example, prostate-specific antigen (PSA) for detection, or suspicion, of prostate cancer (9). Additional hormonal tests, for example, prolactin, and luteinizing hormone, are performed when low testosterone levels are detected. If any abnormality is observed, referral to an endocrinologist may be indicated (10,11).

Although physical examination and laboratory evaluation of most men with ED may not reveal the exact diagnosis, these opportunities to identify critical comorbid conditions should not be missed (12).

Figure 1 gives the minimal diagnostic evaluation (basic work-up) in patients with ED.
2.2.2 **Cardiovascular system and sexual activity: the patient at risk**

Patients who seek treatment for sexual dysfunction have a high prevalence of cardiovascular disease. The cardiac risks associated with sexual activity are well established. Epidemiological surveys have emphasised the association between cardiovascular and metabolic risk factors and sexual dysfunction in men and women (13). ED can improve the sensitivity of screening for asymptomatic cardiovascular disease in men with diabetes (14,15). ED significantly increases the risk of cardiovascular disease, coronary heart disease, stroke, and all-cause mortality, and the increase is probably independent of conventional cardiovascular risk factors (16).

There has been an extensive investigation of the pharmacological properties of phosphodiesterase 5 inhibitors (PDE5Is), including their effects on cardiac smooth muscle activity and overall cardiovascular safety. The EAU Guidelines recommendations given here for treating men with ED have been adapted from previously published recommendations from the Princeton Consensus conferences on sexual dysfunction and cardiac risk (17-19). The Princeton Consensus (Expert Panel) Conference is dedicated to optimizing sexual function and preserving cardiovascular health. A total of three consensus papers have been published (17-19). The Third Princeton Consensus had two primary objectives. The first focused on evaluation and management of cardiovascular risk in men with ED and no known cardiovascular disease, with particular emphasis on identification of men with ED who may require additional cardiological work-up. The second objective focused on re-evaluation and modification of previous recommendations for evaluation of cardiac risk associated with sexual activity in men with known cardiovascular disease. The recommendations built on those developed during the first and second Princeton Consensus Conferences; first, emphasising the use of exercise ability and stress testing to ensure that each man’s cardiovascular health is consistent with the physical demands of sexual activity before prescribing treatment for ED; and second, highlighting the link between ED and...
cardiovascular disease, which may be asymptomatic and benefit from cardiovascular risk reduction (19). Patients with ED can be stratified into three cardiovascular risk categories (Table 4), which can be used as the basis for a treatment algorithm for initiating or resuming sexual activity (Figure 2). It is also possible for the clinician to estimate the risk of sexual activity in most patients from their level of exercise tolerance, which can be determined when taking the patient’s history.

Figure 2: Treatment algorithm for determining level of sexual activity according to cardiac risk in ED (based on 3rd Princeton Consensus) (19)

- Sexual inquiry of all men
- ED confirmed
- Exercise ability
- Low risk
- Intermediate risk
- High risk
- Stress test
- Pass
- Fail
- Advice, treat ED
- Cardiologist

*Sexual activity is equivalent to walking 1 mile on the flat in 20 min or briskly climbing two flights of stairs in 10 s.

**Sexual activity is equivalent to 4 min of the Bruce treadmill protocol.
2.2.2.1 Low-risk category
The low-risk category includes patients who do not have any significant cardiac risk associated with sexual activity. Low risk is typically implied by the ability to perform exercise of modest intensity, which is defined as ≥ 6 “metabolic equivalents of energy expenditure in the resting state” (METs) without symptoms. According to current knowledge of the exercise demand or emotional stress associated with sexual activity, low-risk patients do not need cardiac testing or evaluation before the initiation or resumption of sexual activity or therapy for sexual dysfunction.

2.2.2.2 Intermediate- or indeterminate-risk category
The intermediate- or indeterminate-risk category consists of patients with an uncertain cardiac condition or patients whose risk profile requires testing or evaluation before the resumption of sexual activity. Based upon the results of testing, these patients may be moved to either the high- or low-risk group. A cardiology consultation may be needed in some patients to help the primary physician determine the safety of sexual activity.

2.2.2.3 High-risk category
High-risk patients have a cardiac condition that is sufficiently severe and/or unstable for sexual activity to carry a significant risk. Most high-risk patients have moderate-to-severe symptomatic heart disease. High-risk individuals should be referred for cardiac assessment and treatment. Sexual activity should be stopped until the patient’s cardiac condition has been stabilised by treatment, or a decision made by the cardiologist and/or internist that it is safe to resume sexual activity.

2.2.3 Specialised diagnostic tests
Most patients with ED can be managed within the sexual care setting, conversely, some patients may need specific diagnostic tests (Tables 5 and 6).

2.2.3.1 Nocturnal penile tumescence and rigidity test
The nocturnal penile tumescence and rigidity (NPTR) assessment should be done on at least two nights. A functional erectile mechanism is indicated by an erectile event of at least 60% rigidity recorded on the tip of the penis that lasts for ≥ 10 min (20).

2.2.3.2 Intracavernous injection test
The intracavernous injection test gives limited information about vascular status. A positive test is a rigid erectile response (unable to bend the penis) that appears within 10 min after the intracavernous injection and lasts for 30 min (21). This response indicates a functional, but not necessarily normal, erection, and the erection may coexist with arterial insufficiency and/or veno-occlusive dysfunction (22). A positive test shows that a patient will respond to the intracavernous injection programme. The test is inconclusive as a diagnostic procedure and duplex Doppler study of the penis should be requested, if clinically warranted.

2.2.3.3 Duplex ultrasound of the penis
A peak systolic blood flow > 30 cm/s, an end-diastolic velocity of < 3 cm/s and a resistance index > 0.8 are generally considered normal (21). Further vascular investigation is unnecessary when a Duplex examination is normal.

2.2.3.4 Arteriography and dynamic infusion cavernosometry or cavernosography
Arteriography and dynamic infusion cavernosometry or cavernosography (DICC) should be performed only in patients who are being considered for vascular reconstructive surgery (23).

2.2.3.5 Psychiatric assessment
Patients with psychiatric disorders must be referred to a psychiatrist who is particularly interested in ED. In younger patients (< 40 years) with long-term primary ED, psychiatric assessment may be helpful before any organic assessment is carried out.

2.2.3.6 Penile abnormalities
Surgical correction may be needed for patients with ED due to penile abnormalities, e.g. hypospadias, congenital curvature, or Peyronie’s disease with preserved rigidity.

2.2.4 Patient education - consultation and referrals
Consultation with the patient should include a discussion of the expectations and needs of both the patient and his stable sexual partner, if available. It should also review both the patient’s and partner’s understanding
of ED, the results of diagnostic tests, and provide a rational selection of treatment options. Patient and partner education is an essential part of ED management (24,25).

Table 5: Indications for specific diagnostic tests

2.2.5 Guidelines for the diagnostic evaluation of ED

| Clinical use of validated questionnaire related to ED may help to assess all sexual function domains and the effect of a specific treatment modality. |
|-------------------------------------------------------------------------------------------------------------------------------------|----|---|
| Physical examination is needed in the initial assessment of men with ED to identify underlying medical conditions that may be associated with ED. | 3  | B |
| Routine laboratory tests, including glucose-lipid profile and total testosterone, are required to identify and treat any reversible risk factors and lifestyle factors that can be modified. | 4  | B |
| Specific diagnostic tests are indicated by only a few conditions.                                                                      | 4  | B |

2.2.6 References

3. TREATMENT OF ERECTILE DYSFUNCTION

3.1 Treatment options
The primary goal in the management strategy of a patient with ED is to determine its etiology and treat it when possible, and not to treat the symptom alone. ED may be associated with modifiable or reversible risk factors, including lifestyle or drug-related factors. These factors may be modified either before, or at the same time as, specific therapies are used.

As a rule, ED can be treated successfully with current treatment options, but cannot be cured. The only exceptions are psychogenic ED, post-traumatic arteriogenic ED in young patients, and hormonal causes (e.g., hypogonadism and hyperprolactinaemia), which potentially can be cured with specific treatment.

Most men with ED will be treated with therapeutic options that are not cause specific. This results in a structured treatment strategy that depends on efficacy, safety, invasiveness and cost, as well as patient preference (1). To properly counsel patients with ED, physicians must be fully informed of all available treatment options. In this context, physician-patient (partner) dialogue is essential throughout the management of ED.

The assessment of treatment options must consider patient and partner satisfaction and other QoL factors as well as efficacy and safety. A treatment algorithm for ED is given in Figure 3.
3.2 Lifestyle management in ED with concomitant risk factors

The basic work-up of the patient must identify reversible risk factors for ED. Lifestyle changes and risk factor modification must precede or accompany any pharmacological treatment.

The potential benefits of lifestyle changes may be particularly important in individuals with ED and specific comorbid cardiovascular or metabolic disorders, such as diabetes or hypertension (2–4). Besides
improving erectile function, aggressive lifestyle changes may also benefit overall cardiovascular and metabolic health, with recent studies supporting the potential of lifestyle intervention to benefit both ED and overall health (5,6).

Although further studies are needed to clarify the role of lifestyle changes in management of ED and related cardiovascular disease, lifestyle changes can be recommended alone or combined with PDE5 therapy. Some studies have suggested that the therapeutic effects of PDE5Is may be enhanced when other comorbidities or risk factors are aggressively managed (7). A significant improvement can be expected as soon as after 3 months of initiating lifestyle changes (8).

However, these results have yet to be confirmed in well-controlled, long-term studies. As a result of the success of pharmacological therapy for ED, clinicians need to provide specific evidence for the benefits of lifestyle change, and hopefully, future research will show this.

3.3 Erectile dysfunction after radical prostatectomy

Use of proerectile drugs following RP is important in achieving postoperative erectile function. Several trials have shown higher rates of erectile function recovery after RP in patients receiving any drug (therapeutic or prophylactic) for ED. Early compared with delayed erectile rehabilitation brings forward the natural healing time of potency (9).

Historically, the treatment options for postoperative ED have included intracavernous injections (10), urethral microsuppository (11), vacuum device therapy (12), and penile implants (13). Intracavernous injections and penile implants are still suggested as second- and third-line treatments, respectively, when oral compounds are not adequately effective or contraindicated for postoperative patients (Sections 3.6 and 3.7). The management of post-RP ED has been revolutionised by the advent of PDE5Is, with their demonstrated efficacy, ease of use, good tolerability, excellent safety, and positive impact on QoL. Overall, it must be emphasized that post-RP ED patients are poor responders to PDE5Is. However, PDE5Is are the first-line choice of oral pharmacotherapy for post-RP ED in patients who have undergone nerve-sparing (NS) surgery. The choice of PDE5Is as first-line treatment is controversial because the experience (surgical volume) of the surgeon is a key factor in preserving postoperative erectile function, in addition to patient age and NS technique (14–16). In fact, PDE5Is are most effective in patients who have undergone a rigorous NS procedure, which is more commonly performed by large-volume surgeons (14,15).

Early use of high-dose sildenafil after RP has been suggested to be associated with preservation of smooth muscle within the corpora cavernosa (17). Daily sildenafil also results in a greater return of spontaneous normal erectile function after RP compared to placebo following bilateral NSRP in patients who were fully potent before surgery (18,19). The response rate to sildenafil treatment for ED after RP in different trials has ranged from 35% to 75% among those who underwent NSRP and from 0% to 15% among those who underwent non-NSRP (18-21).

Effectiveness of tadalafil and vardenafil as on-demand treatment has been evaluated in post-RP ED.

• A large multicentre trial in Europe and USA has studied tadalafil in patients with ED following bilateral NS surgery. Erectile function was improved in 71% of patients treated with 20 mg tadalafil versus 24% of those treated with placebo, while the rate of successful intercourse attempts was 52% with 20 mg tadalafil versus 26% with placebo (22).

• Similarly, vardenafil has been tested in patients with ED following either unilateral or bilateral NS surgery in a randomised, multicentre, prospective, placebo-controlled study in North America (23). Following bilateral NSRP, erectile function improved by 71% and 60% with 10 and 20 mg vardenafil, respectively. An extended analysis of the same patients undergoing NSRP has underlined the benefit of vardenafil compared to placebo regarding intercourse satisfaction, hardness of erection, orgasmic function, and overall satisfaction with sexual experience (24).

A randomised, double-blind, double-dummy, multicentre, parallel-group study in 87 centres across Europe, Canada, South Africa and the USA, compared on-demand and nightly dosing of vardenafil in men with ED following bilateral NSRP. In patients whose IIEF erectile function domain (IIEF-EF) score was ≥ 26 before surgery, vardenafil was efficacious when used on demand, supporting a paradigm shift towards on-demand dosing with PDE5Is in post-RP ED (25). A prospective, randomised, open label, multicentre American study in men with normal erection who underwent bilateral NSRP showed that oral and intraurethral treatment has the same benefit for penile recovery within the first year after surgery (26).

Patients who do not respond to oral PDE5Is after NSRP may be treated with prophylactic intracorporeal alprostadil (27,28). Penile prosthesis remains a satisfactory approach for patients who do not respond to either oral or intracavernous pharmacotherapy or to a vacuum device (29).
3.4 Causes of ED that can be potentially treated with a curative intent

3.4.1 Hormonal causes

The advice of an endocrinologist may be beneficial for managing patients with hormonal abnormalities. Testosterone deficiency is either a result of primary testicular failure or secondary to pituitary/hypothalamic causes, including a functional pituitary tumour resulting in hyperprolactinaemia.

Testosterone replacement therapy (intramuscular, oral, or transdermal) is effective, but should only be used after other endocrinological causes for testicular failure have been excluded (30). Testosterone replacement is controversial in men with a history of prostate carcinoma (LE: 4) (31). There is limited evidence suggesting that such treatment may not pose an undue risk of prostate cancer recurrence or progression (32). Before initiating testosterone replacement, digital rectal examination, serum PSA test, hematocrit, liver function tests and lipid profile should be performed (33). Patients given androgen therapy should be monitored for clinical response, elevated hematocrit and development of hepatic or prostatic disease. Testosterone therapy is contraindicated in patients with untreated prostate cancer or unstable cardiac disease.

3.4.2 Post-traumatic arteriogenic ED in young patients

In young patients with pelvic or perineal trauma, surgical penile revascularisation has a 60-70% long-term success rate (34). The lesion must be demonstrated by duplex Doppler study of the penis and confirmed by penile pharmacoarteriography. Corporeal veno-occlusive dysfunction is a contraindication to revascularisation and must be excluded by DICC. Vascular surgery for veno-occlusive dysfunction is no longer recommended because of poor long-term results (35).

3.4.3 Psychosexual counselling and therapy

For patients with a significant psychological problem, psychosexual therapy may be given either alone or with another therapeutic approach. Psychosexual therapy requires ongoing follow-up and has had variable results (36).

3.5 First-line therapy

3.5.1 Oral pharmacotherapy

PDE5 hydrolysates cGMP in the cavernosum tissue. Inhibition of PDE5 results in smooth muscle relaxation with increased arterial blood flow, leading to compression of the subtunical venous plexus and penile erection (37).

Three potent selective PDE5Is have been approved by the European Medicines Agency (EMA) for the treatment of ED. They are not initiators of erection and require sexual stimulation to facilitate an erection.

3.5.1.1 Sildenafil

Sildenafil was launched in 1998 and was the first PDE5I available on the market. Efficacy is defined as an erection with rigidity sufficient for vaginal penetration. Sildenafil is effective from 30-60 min after administration. Its efficacy is reduced after a heavy, fatty meal due to prolonged absorption. It is administered in doses of 25, 50 and 100 mg. The recommended starting dose is 50 mg and should be adapted according to the patient’s response and side effects. Efficacy may be maintained for up to 12 h (38). The pharmacokinetic data of sildenafil are presented in Table 7. Adverse events (Table 8) are generally mild in nature and self-limited by continuous use. The drop-out rate due to adverse events is similar to that with placebo (39).

After 24 weeks in a dose-response study, improved erections were reported by 56%, 77% and 84% of a general ED population taking 25, 50 and 100 mg sildenafil, respectively, compared to 25% of men taking placebo (40). Sildenafil significantly improves patient scores in IIEF, sexual encounter profile (SEP)2, SEP3, and general assessment question (GAQ) and treatment satisfaction.

The efficacy of sildenafil in almost every subgroup of patients with ED has been successfully established. In patients with diabetes, 66.6% reported improved erections (GAQ) and 63% successful intercourse attempts compared to 28.6% and 33% of men taking placebo, respectively (41).

3.5.1.2 Tadalafil

Tadalafil was licenced for treatment of ED in February 2003 and is effective from 30 min after administration, with peak efficacy after about 2 h. Efficacy is maintained for up to 36 h (42) and is not affected by food. Ten and 20 mg doses have been approved for on-demand treatment of ED. The recommended starting dose is 10 mg and should be adapted according to the patient’s response and side effects. Pharmacokinetic data of tadalafil are presented in Table 7. Adverse events (Table 8) are generally mild in nature and self-limited by continuous use. The drop-out rate due to adverse events is similar to that with placebo (43).

In premarketing studies, after 12 weeks of treatment and in a dose-response study, improved erections were reported by 67% and 81% of a general ED population taking 10 and 20 mg tadalafil, respectively, compared to 35% of men in the control placebo group (43). Tadalafil significantly improves patient scores in IIEF, SEP2, SEP3, and GAQ and treatment satisfaction. These results have been confirmed in
postmarketing studies (44).

Tadalafil also improves erections in difficult-to-treat subgroups. In patients with diabetes, 64% reported improved erections (i.e., improved GAQ) versus 25% of patients in the control group, and the change in the final score for IIEF-EF was 7.3 compared to 0.1 for placebo (45). Nevertheless diabetic patients remain poor responders to tadalafil on demand, with a successful intercourse rates increasing from 21.8% with placebo to 45.4 and 49.9% with 10 and 20 mg of tadalafil on demand respectively (46).

3.5.1.3 Vardenafil

Vardenafil became commercially available in March 2003 and is effective from 30 min after administration. Its effect is reduced by a heavy, fatty meal (> 57% fat). Five, 10 and 20 mg doses have been approved for on-demand treatment of ED. The recommended starting dose is 10 mg and should be adapted according to the patient’s response and side effects. In vitro, it is 10-fold more potent than sildenafil, although this does not necessarily mean greater clinical efficacy (47). Pharmacokinetic data of vardenafil are presented in Table 7. Adverse events (Table 8) are generally mild in nature and self-limited by continuous use, with a drop-out rate similar to that with placebo (48).

After 12 weeks in a dose-response study, improved erections were reported by 66%, 76% and 80% of a general ED population taking 5, 10 and 20 mg vardenafil, respectively, compared with 30% of men taking placebo (49). Vardenafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction. Efficacy has been confirmed in postmarketing studies (50).

Vardenafil improves erections in difficult-to-treat subgroups. In patients with diabetes, the final IIEF-EF score was 19 compared to 12.6 for placebo (51). Nevertheless, again, diabetic patients remain poor responders to vardenafil on demand with a successful intercourse rates increasing from 23% with placebo to 49% and 54% with 10 and 20 mg of vardenafil on demand, respectively (51).

Recently, a new formulation of vardenafil has been released, in the form of an orodispersible tablet (ODT). ODT formulations offer improved convenience over film-coated formulations and may be preferred by patients. Absorption is unrelated to food intake and they exhibit better bioavailability compared to film-coated tablets (52). The efficacy of vardenafil ODT has been demonstrated in several randomised controlled trials and did not seem to differ from the regular formulation (53-56).

3.5.1.4 Choice or preference between the different PDEs inhibitors

To date, no data are available from double- or triple-blind multicentre studies comparing the efficacy and/or patient preference for sildenafil, tadalafil, and vardenafil. Choice of drug will depend on the frequency of intercourse (occasional use or regular therapy, 3-4 times weekly) and the patient’s personal experience.

Patients need to know whether a drug is short- or long-acting, its possible disadvantages, and how to use it.

3.5.1.5 On-demand or chronic use of PDE5 inhibitors

Animal studies have shown that chronic use of PDE5Is improves or prevents significantly the intracavernous structure alterations due to age, diabetes, or surgical damage (57-62). No data exists for a human population.

In humans, a randomised study (n = 145) has shown that daily tadalafil led to a significantly higher IIEF-EF score and higher completion of successful intercourse attempts compared to on-demand tadalafil (63). Two major randomised double-blind studies, using 5 and 10 mg/day tadalafil for 12 weeks (n = 268) (64) and 2.5 and 5 mg/day tadalafil for 24 weeks (n = 268) (65), have shown that daily dosing was well tolerated and significantly improved erectile function. However, these studies lacked a comparative on-demand treatment arm. An open-label extension was carried out for both studies in 234 patients for 1 year and 238 patients for 2 years. Tadalafil, 5 mg once daily, was shown to be well tolerated and effective (66). Tadalafil, 5 mg once daily, therefore provides an alternative to on-demand dosing of tadalafil for couples who prefer spontaneous rather than scheduled sexual activities or who anticipate frequent sexual activity, with the advantage that dosing and sexual activity no longer need to be temporally linked. Nevertheless, in the 1-year open-label 5 mg tadalafil extension study followed by 4 weeks wash-out, erectile function was not maintained after discontinuation of therapy in most patients (about 75%).

In 2007, tadalafil 2.5 and 5 mg have been approved by the European Medicines Agency (EMA) for daily treatment of ED. According to EMA, patients who anticipate a frequent use of tadalafil (i.e., at least twice weekly) a once daily regimen with tadalafil 2.5 mg or 5 mg might be considered suitable, based on patient choice and the physician’s judgement. In these patients, the recommended dose is 5 mg taken once a day at approximately the same time of day. The dose may be decreased to 2.5 mg once a day based on individual tolerability. The appropriateness of the continuous use of a daily regimen should be reassessed periodically.

A double-blind, placebo-controlled, multicentre, parallel-group study was conducted in 236 men with mild-to-moderate ED randomised to receive 10 mg vardenafil once daily plus on-demand placebo for 12 or 24 weeks, or once-daily placebo plus on-demand 10 mg vardenafil for 24 weeks, followed by 4 weeks wash-out.
Despite preclinical evidence, the results suggested that once-daily dosing of 10 mg vardenafil does not offer any sustainable effect after cessation of treatment compared to on-demand administration in patients with mild-to-moderate ED. Other studies (open-label, randomised, crossover studies with limited patient numbers) have shown that chronic, but not on-demand, tadalafil treatment improves endothelial function with a sustained effect after its discontinuation (68, 69). This has been confirmed in another study of chronic sildenafil in men with type 2 diabetes (70).

Recently, in a double-blind, placebo-controlled study of 298 men with diabetes and ED, 2.5 and 5 mg tadalafil once daily for 12 weeks was efficacious and well tolerated. This regimen provides an alternative to on-demand treatment for some men with diabetes (71).

3.5.1.6 Safety issues for PDE5 inhibitors

3.5.1.6.1 Cardiovascular safety

Clinical trial results and post-marketing data of sildenafil, tadalafil, and vardenafil have demonstrated no increase in myocardial infarction rates in patients receiving PDE5Is, as part of either double-blind, placebo-controlled trials or open-label studies, or compared to expected rates in age-matched male populations. None of the PDE5Is had an adverse effect on total exercise time or time-to-ischaemia during exercise testing in men with stable angina (72, 73). In fact, they may even improve exercise tests. Sildenafil does not alter cardiac contractility, cardiac output or myocardial oxygen consumption according to available evidence. Chronic or on-demand use is well tolerated with a similar safety profile.

3.5.1.6.2 Nitrates are contraindicated with PDE5 inhibitors

Organic nitrates (e.g., nitroglycerine, isosorbide mononitrate, and isosorbide dinitrate) and other nitrates preparations used to treat angina, as well as amyl nitrite or amyl nitrate (“poppers” used for recreation), are absolute contraindications for the use of PDE5Is. They result in cGMP accumulation and unpredictable falls in blood pressure and symptoms of hypotension. The duration of interaction between organic nitrates and PDE5Is depends upon the PDE5I and nitrate used.
If a PDE5I is taken and the patient develops chest pain, nitroglycerine must be withheld for at least 24 h if sildenafil (and probably also vardenafil) is used (half-life, 4 h), and for at least 48 h if tadalafil is used (half-life, 17.5 h).

If a patient develops angina while taking a PDE5I, other agents may be given instead of nitroglycerine until the appropriate time has passed. If nitroglycerine must be reintroduced following administration of a PDEI, the patient should receive it only after an appropriate interval has elapsed, as described above, and under close medical observation.

3.5.1.6.3 Antihypertensive drugs
Co-administration of PDE5Is with antihypertensive agents (angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, calcium blockers, β-blockers, and diuretics) may result in small additive decreases in blood pressure, which are usually minor. In general, the adverse event profile of a PDE5I is not made worse by a background of antihypertensive medication, even when the patient is taking several antihypertensive agents.

3.5.1.6.4 α-Blocker interactions
All PDE5Is show some interaction with α-blockers, which under some conditions may result in orthostatic hypotension.

- Sildenafil labelling currently advises that 50 or 100 mg sildenafil should be used with caution in patients taking an α-blocker (especially doxazosin). Hypotension is more likely to occur within 4 h following treatment with an α-blocker. A starting dose of 25 mg is recommended.
- Concomitant treatment with vardenafil should only be initiated if the patient has been stabilised on his alpha-blocker therapy.
- Co-administration of vardenafil with tamsulosin is not associated with clinically significant hypotension (74).
- Tadalafil is not recommended in patients taking doxazosin but this is not the case for tamsulosin, 0.4 mg (75).

These interactions are more pronounced when PDE5Is are given to healthy volunteers not previously taking α-blockers. Therefore, patients should be stable on α-blocker therapy prior to initiating combined treatment, and that the lowest dose should be started initially of PDE5Is. Further research is needed into the interaction between other PDE5Is and other α-blockers (e.g., alfuzosin, once-daily), or mixed α/β-blockers (e.g., carvedilol and labetalol).

3.5.1.6.5 Dosage adjustment
Drugs that inhibit the CYP34A pathway will inhibit the metabolic breakdown of PDE5Is. They include ketoconazole, itraconazole, erythromycin, clarithromycin, and HIV protease inhibitors (ritonavir and saquinavir). Such agents may increase blood levels of PDE5Is, so that lower doses of PDE5Is are necessary.

However, other agents, such as rifampin, phenobarbital, phenytoin and carbamazepine, may induce CYP34A and enhance the breakdown of PDE5Is, so that higher doses of PDE5Is are required. Severe kidney or hepatic dysfunction may require dose adjustments or warnings.

3.5.1.7 Management of non-responders to PDE5 inhibitors
The two main reasons why patients fail to respond to a PDE5I are either incorrect drug use or lack of efficacy of the drug. The management of non-responders depends upon identifying the underlying cause.

3.5.1.7.1 Check that the patient has been using a licensed medication
There is a large black market in PDE5Is. The amount of active drug in these medications varies enormously and it is important to check how and from which source the patient has obtained his medication.

3.6.1.7.2 Check that the medication has been properly prescribed and correctly used
The main reason why patients fail to use their medication correctly is inadequate counselling from their physician. The main ways in which a drug may be incorrectly used are:

- failure to use adequate sexual stimulation;
- failure to use an adequate dose;
- failure to wait an adequate amount of time between taking the medication and attempting sexual intercourse.

Lack of adequate sexual stimulation: PDE5Is depend for their action upon the release of NO by the parasympathetic nerve endings in the erectile tissue of the penis. The usual stimulus for NO release is sexual
stimulation, and without adequate sexual stimulation (and NO release), the drugs cannot work.

Oral PDE5Is take different times to reach maximal plasma concentrations (76,77). Although pharmacological activity is achieved at plasma levels well below the maximal plasma concentration, there will be a period of time following oral ingestion of the medication during which the drug is ineffective. Even though all three drugs have an onset of action in some patients within 30 min of oral ingestion, most patients require a longer delay between taking the medication, with at least 60 min being required for men using sildenafil and vardenafil, and up to 2 h being required for men using tadalafil (78-80).

Absorption of sildenafil can be delayed by a meal, and absorption of vardenafil can be delayed by a fatty meal (81). Absorption of tadalafil is less affected provided there is enough delay between oral ingestion and an attempt at sexual intercourse (77).

It is possible to wait too long after taking medication before attempting sexual intercourse. The half-life of sildenafil and vardenafil is about 4 h, suggesting that the normal window of efficacy is 6-8 h following drug ingestion, although responses following this time period are well recognised. Tadalafil has a longer half-life of ~17.5 h, so the window of efficacy is much longer at ~36 h.

For financial reasons, some physicians may prescribe only lower doses of a drug. It is important to check that the patient has had an adequate trial of the maximal dose of the drug. Data suggest an adequate trial involves at least six attempts with a particular drug (82).

Data from uncontrolled studies suggests patient education can help salvage an apparent non-responder to a PDE5I. After emphasising the importance of dose, timing, and sexual stimulation to the patient, erectile function can be effectively restored following re-administration of the relevant PDE5I (83-85).

One study (84) went further, and in those patients who still did not respond to the PDE5I, a second-line adjustment was instituted. Patients taking tadalafil were advised to wait at least 2 h between oral ingestion and attempting intercourse. Patients taking vardenafil were advised to use the drug only after a fast. In both patient groups, further apparent non-responders were salvaged. No patients using sildenafil were included in this study.

3.5.1.7.3 Possible manoeuvres in patients correctly using a PDE5 inhibitor

When the patient is using an adequate dose of the drug properly and the response is still inadequate, there are several changes that may improve drug efficacy, although the evidence supporting these interventions is limited.

Erectile dysfunction is typically a symptom of an underlying condition, such as diabetes, hypertension, or dyslipidaemia. There is evidence suggesting that, in patients with hypogonadism, normalisation of serum testosterone might improve response to a PDE5I (86). Modification of other risk factors may be also be beneficial as discussed in section 3.2.

A randomised trial has suggested that vardenafil benefits non-responders to sildenafil (87), but because of poor study design, the results are considered to overstate the benefits of switching PDE5Is. However, a randomised, open-label, crossover trial comparing sildenafil and tadalafil has indicated that some patients might respond better to one PDE5I than to another (88). According to the IIEF-EF score, 17% of patients had a better response (≥ 5 points) to tadalafil than to sildenafil, while 14% had a better response to sildenafil than tadalafil.

Although these differences might be explained by variation in drug pharmacokinetics, they do raise the possibility that, despite an identical mode of action, switching to a different PDE5I might be helpful.

Two non-randomized trials have suggested that daily dosing with a PDE5I might salvage some non-responders to intermittent dosing. In one trial (89), some men benefited from regular dosing with either vardenafil or tadalafil, while in the other trial (84) daily dosing with tadalafil salvaged some men who had failed to respond to intermittent dosing with a PDE5I.

Currently, there are no randomised trials to support this intervention. Although tadalafil is licensed for daily dosing at 2.5 and 5 mg, neither sildenafil nor vardenafil are licensed for use in this way.

If drug treatment fails, then patients should be offered an alternative therapy such as intracavernosal injection therapy or use of a vacuum erection device.

3.5.2 Vacuum erection devices

Vacuum erection devices (VEDs) provide passive engorgement of the corpora cavernosa, together with a constrictor ring placed at the base of the penis to retain blood within the corpora. Thus, erections with these devices are not normal because they do not use physiological erection pathways. Efficacy, in terms of erections satisfactory for intercourse, is as high as 90%, regardless of the cause of ED and satisfaction rates range between 27% and 94% (90). Men with a motivated, interested, and understanding partner report the highest satisfaction rates. Long-term use of VEDs decreases to 50-64% after 2 years (91). Most men who discontinue use of VEDs do so within 3 months.

The commonest adverse events include pain, inability to ejaculate, petechiae, bruising, and
numbness, which occur in < 30% of patients (92). Serious adverse events (skin necrosis) can be avoided if patients remove the constriction ring within 30 min. VEDs are contraindicated in patients with bleeding disorders or on anticoagulant therapy.

VEDs may be the treatment of choice in well-informed older patients with infrequent sexual intercourse and comorbidity requiring non-invasive, drug-free management of ED (90).

3.5.3 Shockwave therapy
Recently, the use of low-intensity extracorporeal shock wave therapy was proposed as a novel treatment for ED (93). In the first randomised, double-blind, sham-controlled study, it was demonstrated that low-intensity extracorporeal shock wave therapy had a positive short-term clinical and physiological effect on the erectile function of men who respond to oral PDE5Is (94). Moreover, there are preliminary data showing improvement in penile hemodynamics and endothelial function, as well as IIEF-EF domain score in severe ED patients who are poor responders to PDE5Is (95). The feasibility and tolerability of this treatment, coupled with its potential rehabilitative characteristics, make it an attractive new therapeutic option for men with ED. However, current data are limited and clear recommendations cannot be given. Data regarding the mechanism of action of this procedure are still lacking. In a diabetic rat model, low-intensity extracorporeal shock wave therapy ameliorated diabetes mellitus associated ED by promoting regeneration of nNOS-positive nerves, endothelium, and smooth muscle in the penis. These beneficial effects appear to be mediated by recruitment of endogenous mesenchymal stem cells (MSCs) (96).

3.6 Second-line therapy
Patients not responding to oral drugs may be offered intracavernous injections. Success rate is high (85%) (97,98). Intracavernous administration of vasoactive drugs was the first medical treatment for ED more than 20 years ago (99).

3.6.1 Intracavernous injections
3.6.1.1 Alprostadil
Alprostadil (CaverjectTM, Edex/ViridalTM) was the first and only drug approved for intracavernous treatment of ED (99). Intracavernous alprostadil is most efficacious as monotherapy at a dose of 5-40 μg; although the 40 μg dose is not registered in every European country. The erection appears after 5-15 min and lasts according to the dose injected. An office-training programme (one or two visits) is required for the patient to learn the correct injection process. In cases of limited manual dexterity, the technique may be taught to their partners. The use of an automatic special pen that avoids a view of the needle can resolve fear of penile puncture and simplifies the technique.

Efficacy rates for intracavernous alprostadil of > 70% have been found in general ED populations, as well as in patient subgroups (e.g., diabetes or cardiovascular disease), with reported sexual activity after 94% of the injections and satisfaction rates of 87-93.5% in patients and 86-90.3% in partners (100-102).

Complications of intracavernous alprostadil include penile pain (50% of patients reported pain but pain reported only after 11% of total injections), prolonged erections (5%), priapism (1%), and fibrosis (2%) (103). Pain is usually self-limited after prolonged use. It can be alleviated with the addition of sodium bicarbonate or local anaesthesia (104,105). Cavernosal fibrosis (from a small hematoma) usually clears within a few months after temporary discontinuation of the injection program. However, tunical fibrosis suggests early onset of La Peyronie’s disease and may indicate stopping intracavernosal injections indefinitely. Systemic side effects are uncommon. The most common is mild hypotension, especially when using higher doses.

Contraindications include men with a history of hypersensitivity to alprostadil, men at risk of priapism, and men with bleeding disorders.

Despite these favourable data, intracavernous pharmacotherapy is associated with high drop-out rates and limited compliance. Drop-out rates of 41-68% have been described (106-108), with most drop outs occurring within the first 2-3 months. In a comparative study, alprostadil monotherapy had the lowest discontinuation rate (27.5%) compared to overall drug combinations (37.6%), with an attrition rate after the first few months of therapy of 10% per year. Reasons for discontinuation included desire for a permanent modality of therapy (29%), lack of a suitable partner (26%), poor response (23%) (especially among early drop-out patients), fear of needles (23%), fear of complications (22%), and lack of spontaneity (21%). Careful counselling of patients during the office-training phase as well as close follow-up is important in addressing patient withdrawal from an intracavernous injection programme (109).

Today, intracavernous pharmacotherapy is considered a second-line treatment. Patients not responding to oral drugs may be offered intracavernous injections with a high success rate of 85%. Most long-term injection users can switch to sildenafil despite underlying pathophysiology (110-112). However, almost one-third of long-term intracavernous injections users who subsequently also responded to sildenafil preferred to continue with an intracavernous injection programme (112,113).
3.6.1.2 Combination therapy

Combination therapy enables a patient to take advantage of the different modes of action of the drugs being used, as well as alleviating side effects by using lower doses of each drug.

- Papaverine (20-80 mg) was the first oral drug used for intracavernous injections. It is most commonly used in combination therapy today due to its high incidence of side effects as monotherapy.
- Phentolamine has been used in combination therapy to increase efficacy. As monotherapy, it produces a poor erectile response.
- Sparse data in the literature support the use of other drugs, such as vasoactive intestinal peptide (VIP), NO donors (linsidomine), forskolin, potassium channel openers, moxisylyte or calcitonin gene-related peptide (CGRP), usually combined with the main drugs (114,115). Most combinations are not standardised and some drugs have limited availability worldwide.
- Papaverine (7.5-45 mg) plus phentolamine (0.25-1.5 mg), and papaverine (8-16 mg) plus phentolamine (0.2-0.4 mg) plus alprostadil (10-20 μg), have been widely used with improved efficacy rates, although they have never been licensed for ED (116-118). The triple combination regimen of papaverine, phentolamine and alprostadil has the highest efficacy rates, reaching 92%; this combination has similar side effects as alprostadil monotherapy, but a lower incidence of penile pain due to lower doses of alprostadil. However, fibrosis is more common (5-10%) when papaverine is used (depending on total dose). In addition, mild hepatotoxicity has been reported with papaverine (119).

Despite high efficacy rates, 5-10% of patients do not respond to combination intracavernous injections. The combination of sildenafil with intracavernous injection of the triple combination regimen may salvage as many as 31% of patients who do not respond to the triple combination alone (120). However, combination therapy is associated with an incidence of adverse effects in 33% of patients, including dizziness in 20% of patients. This strategy can be considered in carefully selected patients before proceeding to a penile implant.

3.6.1.3 Intraurethral alprostadil

A specific formulation of alprostadil (125-1000 μg) in a medicated pellet (MUSE™) has been approved for use in ED (121). A vascular interaction between the urethra and the corpora cavernosa enables drug transfer between these structures (121). Erections sufficient for intercourse are achieved in 30-65.9% of patients. In clinical practice, only the higher doses (500 and 1000 μg) have been used with low consistency response rates (121-123). The application of a constriction ring at the root of the penis (ACTIS™) may improve efficacy (123,124).

The most common adverse events are local pain (29-41%) and dizziness with possible hypotension (1.9-14%). Penile fibrosis and priapism are very rare (< 1%). Urethral bleeding (5%) and urinary tract infections (0.2%) are adverse events related to the mode of administration.

Efficacy rates are significantly lower than intracavernous pharmacotherapy (125). Intraurethral pharmacotherapy is a second-line therapy and provides an alternative to intracavernous injections in patients who prefer a less-invasive, although less-eficacious treatment.

3.7 Third-line therapy (penile prostheses)

The surgical implantation of a penile prosthesis may be considered in patients who do not respond to pharmacotherapy or who prefer a permanent solution to their problem. The two currently available classes of penile implants include inflatable (2- and 3-piece) and malleable devices (126-129).

Most patients prefer the three-piece inflatable devices due to the more “natural” erections obtained. The three-piece inflatable penile include a separate reservoir placed in the abdominal cavity. Three-piece devices provide the best rigidity and the best flaccidity because they will fill every part of the corporal bodies. However, the two-piece inflatable prosthesis can be a viable option among patients who are deemed high risk of complications with reservoir placements. Malleable prostheses result in a firm penis, which may be manually placed in an erect or flaccid state (126-129).

There are two main surgical approaches for penile prosthesis implantation: peno-scrotal and infrapubic (126-129). The penoscrotal approach provides an excellent exposure, it affords proximal crural exposure if necessary, avoids dorsal nerve injury and permits direct visualisation of pump placement. However, with this approach the reservoir is blindly placed into the retropubic space, which can be a problem in patients with a history of major pelvic surgery (mainly radical cystectomy). The infrapubic approach has the advantage of reservoir placement under direct vision but the implantation of the pump may be more challenging, and patients are at a slightly increased risk of dorsal nerve injury. Revision surgery is associated with decreased outcomes and may be more challenging.

3.7.1 Efficacy and satisfaction rates

Prosthesis implantation has one of the highest satisfaction rates (92-100% in patients and 91-95% in partners) among the treatment options for ED based on appropriate consultation (130-137). Mulhall and colleagues
have used the IIEF and the Erectile Dysfunction Index for Treatment Satisfaction (EDITS) at 3-month intervals following implantation of inflatable penile prostheses. There was a continued improvement in scores for the IIEF and EDITS stabilised 9-12 months following surgery. All variables, including erection, ejaculation, orgasm, and overall sexual satisfaction, improved above baseline values at 1 year after surgery. However, at 3 months following surgery, the results were less satisfactory, suggesting that postoperative counselling and encouragement of patients is important to obtain ultimate satisfaction and positive outcomes at 9-12 months (134).

In a long-term multicentre study of the AMS 700CX three-piece inflatable prosthesis, with a median follow-up of 48 months, 79% of patients were using their device at least twice monthly and 88% would recommend the prosthesis to a friend or relative (135). In another multicentre study with 59 months follow-up, at almost 5 years after surgery, 92.5% of patients were using their prosthesis an average of 1.7 times weekly and excellent or satisfactory results were reported by patients and their partners (132).

Increasingly, in patients with favourable prognosis after RP for prostate cancer, the presence of urinary incontinence and sexual dysfunction (primarily ED and orgasmic dysfunction) is leading doctors to the need for global management of both conditions. Based on appropriate clinical and diagnostic assessments of severity of adverse outcomes depending on patient preference, combination surgery for treatment of ED, with the implant of a penile prosthesis, and stress urinary incontinence (male sling or artificial urinary sphincter) is effective and durable and has an established, definitive role to address this problem (138).

3.7.2 Complications
The two main complications of penile prosthesis implantation are mechanical failure and infection. Several technical modifications of the most commonly used three-piece prosthesis (AMS 700CX/CXR™ and Coloplast Alpha I™) resulted in mechanical failure rates of < 5% after 5 years follow-up (135,139). Careful surgical technique with proper antibiotic prophylaxis against Gram-positive and Gram-negative bacteria reduces infection rates to 2-3% with primary implantation in low-risk patients. The infection rate may be further reduced to 1-2% by implanting an antibiotic-impregnated prosthesis (AMS Inhibizone™) or hydrophilic-coated prosthesis (Coloplast itan™) (140-143).

Higher risk populations include patients undergoing revision surgery, those with impaired host defenses (immunosuppresson, diabetes mellitus, spinal cord injury) or those with penile corporal fibrosis (126-129). Although diabetes is considered to be one of the main risk factors for infection, this is not supported by current data (126-129). Infections, as well as erosions, are significantly higher (9%) in patients with spinal cord injuries (9%) (126-129). Infection requires removal of the prosthesis and antibiotic administration. Alternatively, removal of the infected device with immediate replacement with a new prosthesis has been described using a washout protocol with successful salvages achieved in > 80% of cases (144,145). The majority of revisions are secondary to mechanical failure and combined erosion or infection. Overall, 93% of cases are successfully revised, providing functioning penile prosthesis.

3.7.3 Conclusions
Penile implants are an attractive solution for patients who do not respond to more conservative therapies. There is enough evidence to recommend this approach in patients not responding to less-invasive treatments due to its high efficacy, safety and satisfaction rates.

4. PREMATURE EJACULATION

4.1 Introduction
Although premature ejaculation is a very common male sexual dysfunction, it is poorly understood. Patients are often unwilling to discuss their symptoms and many physicians do not know about effective treatments. As a result, patients may be misdiagnosed or mistreated (1). In addition, there is currently no registered pharmacological treatment for PE.

These guidelines provide an evidence-based analysis (2) of published data on definition, clinical evaluation and treatment. It provides recommendations to clinicians on the diagnosis and treatment of PE, without preempting physician judgement on individual cases.

4.2 Definition of PE
4.2.1 Overview
There have previously been two official definitions of PE, neither of which were universally accepted:

• In the Diagnostic and Statistical Manual of Mental Disorders IV-Text Revision (DSM-IV-TR), PE is defined as a ‘persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity’ (3).

• In the World Health Organization’s International Classification of Diseases-10 (ICD-10), PE is defined as ‘the inability to delay ejaculation sufficiently to enjoy lovemaking, which is manifested by either an occurrence of ejaculation before or very soon after the beginning of intercourse (if a time limit is required: before or within 15 seconds of the beginning of intercourse) or ejaculation occurs in the absence of sufficient erection to make intercourse possible. The problem is not the result of prolonged absence from sexual activity’ (4).

Recently, two more definitions have been proposed:

• The Second International Consultation on Sexual and Erectile Dysfunction defined PE as ‘ejaculation with minimal stimulation and earlier than desired, before or soon after penetration, which causes bother or distress, and over which the sufferer has little or no voluntary control’ (5).

• The International Society for Sexual Medicine (ISSM) has adopted a completely new definition of PE which is the first evidence-based definition, ‘Premature ejaculation is a male sexual dysfunction characterised by ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration; and inability to delay ejaculation on all or nearly all vaginal penetrations; and negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy’. It must be noted that this definition is limited to men with lifelong PE who engage in vaginal intercourse since there are insufficient objective data to propose an evidence-based definition for acquired PE (6).

All four definitions have taken into account the time to ejaculation, the inability to control or delay ejaculation, and negative consequences (bother/distress) from PE. However, the major point of debate is quantifying the time to ejaculation, which is usually described by intravaginal ejaculatory latency time (IELT). Several proposals for updating the definition of PE in the forthcoming DSM-V and ICD-11 have been presented (7-11).

4.2.2 Classifications
Premature ejaculation is classified as ‘lifelong’ (primary) or ‘acquired’ (secondary) (12). Lifelong PE is characterised by onset from the first sexual experience, remains so during life and ejaculation occurs too fast (before vaginal penetration or < 1-2 min after). Acquired PE is characterised by a gradual or sudden onset following normal ejaculation experiences before onset and time to ejaculation is short (usually not as short as in lifelong PE).

Recently, two more PE syndromes have been proposed (11):

• ‘Natural variable PE’ is characterised by inconsistent and irregular early ejaculations, representing a normal variation in sexual performance.

• ‘Premature-like ejaculatory dysfunction’ is characterised by subjective perception of consistent or inconsistent rapid ejaculation during intercourse, while ejaculation latency time is in the normal range or can even last longer. It should not be regarded as a symptom or manifestation of true medical pathology.

The addition of these new types may aid patient stratification, diagnosis and treatment, but their exact role remains to be defined (13).
4.3 Epidemiology

4.3.1 Prevalence

The major problem in assessing the prevalence of PE is the lack of an accurate (validated) definition at the time the surveys were conducted (14). However, epidemiological research has consistently shown that PE, at least according to the DSM-IV definition, is the most common male sexual dysfunction, with prevalence rates of 20-30% (15-17).

The highest prevalence rate of 31% (men aged 18-59 years) was found by the USA NHLS study (16). Prevalence rates from 18 to 29 years, 30 to 39 years, 40 to 49 years and 50 to 59 years were 30%, 32%, 28% and 55%, respectively. These high prevalence rates may be a result of the dichotomous scale (yes/no) in a single question asking if ejaculation occurred too early, as the prevalence rates in European studies have been significantly lower. A British mailed questionnaire survey estimated that the prevalence rate of PE was between 14% (3 months) and 31% (life-time) (18). A French telephone survey of men aged 18 to 69 years estimated the life-time prevalence of early ejaculation at 15%, including 5% who often had experienced ejaculation prior to penetration and 10% who often had ejaculated too rapidly after vaginal intromission (19). A Swedish interview reported an overall prevalence rate of 9% in men aged 18 to 74 years (20), with prevalence by age being 4% for 18-24 years, 7% for 25-34 years, 8% for 35-49 years, 8% for 50-65 years and 14% for 66-74 years. A Danish study about sexual problems using a questionnaire (12 questions) and an interview (23 questions) reported the prevalence rate for PE to be 14% in men aged 51 years (21). An Italian questionnaire survey recorded a prevalence rate of 21% (22). Finally, in a self-administered questionnaire survey in the Netherlands, the prevalence rate was 13% in men aged 50-78 years (23).

The prevalence of PE in the Premature Ejaculation Prevalence and Attitudes (PEPA) survey (a multinational, internet-based survey) was 22.7% (24.0% in the USA, 20.3% in Germany, and 20.0% in Italy) (17). The Global Study of Sexual Attitudes and Behaviors (GSSAB) survey was conducted in men between 40 and 80 years old in 29 different countries using personal and telephone interviews and self-completed mailed questionnaires; it confirmed that the worldwide prevalence of PE was almost 30%. Except for a low reported rate of PE in Middle Eastern countries (10-15%), prevalence was relatively similar throughout the rest of the world (15). Finally, the prevalence rate of PE was 18% in a five-country European Observational study using the IELT and the Premature Ejaculation Profile (PEP) (24), comparable to those obtained in a similarly designed USA observational study (25).

Further research is needed on the prevalence of lifelong and acquired PE. Limited data suggests that the prevalence of lifelong PE, defined as IELT < 1-2 min, is about 2-5% (20, 25). These results are supported by the moderate genetic influence on PE (26) and low prevalence rates of IELT < 1 min (27).

4.3.2 Pathophysiology and risk factors

The aetiology of PE is unknown, with little data to support suggested biological and psychological hypotheses, including anxiety, penile hypersensitivity, and 5-HT receptor dysfunction (5). In addition, the pathophysiology of PE is largely unknown. In contrast to ED, there is no impairment of the physiological events leading up to the forceful expulsion of sperm at the urethral meatus.

A significant proportion of men with ED also experience PE (15). High levels of performance anxiety related to ED may worsen PE, with a risk of misdiagnosing PE instead of the underlying ED.

According to the NHLS, the prevalence of PE is not affected by age (16,17), unlike ED, which increases with age. Premature ejaculation is not affected by marital or income status (16). However, PE is more common in blacks, Hispanic men and men from Islamic backgrounds (28,29) and may be higher in men with a lower educational level (15,16). Other risk factors may include a genetic predisposition (30), poor overall health status and obesity (16), prostate inflammation (31,32), thyroid hormone disorders (33), emotional problems and stress (16,34), and traumatic sexual experiences (15,16).

In the only published study on risk modification/prevention strategies (35), successful eradication of causative organisms in patients with chronic prostatitis and PE produced marked improvements in IELT and ejaculatory control compared to untreated patients.

4.4 Impact on quality of life

Men with PE are more likely to report low satisfaction with their sexual relationship, low satisfaction with sexual intercourse, difficulty relaxing during intercourse, and less frequent intercourse (36,37). However, the negative impact of PE extends beyond sexual dysfunction. PE has a detrimental effect on self-confidence and the relationship with the partner, and may cause mental distress, anxiety, embarrassment and depression (36,38). Sexual drive and overall interest in sex does not appear to be affected by PE (39). However, the partner’s satisfaction with the sexual relationship decreased with increasing severity of the man’s condition (40).

Despite the serious psychological and QoL consequences of PE, few men seek treatment. In the GSSAB survey, 78% of men who self-reported a sexual dysfunction sought no professional help or advice for their sexual problems (15), with men more likely to seek treatment for ED than for PE (15). In the PEPA survey,
only 9% of men with self-reported PE consulted a doctor (17). The main reasons for not discussing PE with their physician are patient embarrassment and a belief that there is no treatment. Physicians are often uncomfortable discussing sexuality with their patients usually because of embarrassment and a lack of training or expertise in treating PE (41,42). Physicians need to encourage patients to talk about PE.

4.5 Diagnosis
Diagnosis of PE is based on the patient’s medical and sexual history (43,44). History should classify PE as lifelong or acquired and determine whether PE is situational (under specific circumstances or with a specific partner) or consistent. Special attention should be given to the duration time of ejaculation, degree of sexual stimulus, impact on sexual activity and QoL, and drug use or abuse. It is also important to distinguish PE from ED.

Many patients with ED develop secondary PE caused by the anxiety associated with difficulty in attaining and maintaining an erection (45). Furthermore, some patients are not aware that loss of erection after ejaculation is normal and may erroneously complain of ED, while the actual problem is PE (46).

There are several overlapping definitions of PE, with four shared factors (Table 7), resulting in a multidimensional diagnosis (47).

Table 9: Common factors in different definitions of ED

<table>
<thead>

</tr>
</thead>
<tbody>
<tr>
<td>Perceived control</td>
</tr>
<tr>
<td>Distress</td>
</tr>
<tr>
<td>Interpersonal difficulty related to the ejaculatory dysfunction</td>
</tr>
</tbody>
</table>

4.5.1 Intravaginal ejaculatory latency time (IELT)
The use of IELT alone is not sufficient to define PE, as there is significant overlap between men with and without PE (24,25). Moreover, IELT has a significant direct effect on perceived control over ejaculation, but not a significant direct effect on ejaculation-related personal distress or satisfaction with sexual intercourse (48). In addition, perceived control over ejaculation has a significant direct effect on both ejaculation-related personal distress and satisfaction with sexual intercourse (each showing direct effects on interpersonal difficulty related to ejaculation).

In everyday clinical practice, self-estimated IELT is sufficient. Self-estimated and stopwatch-measured IELT are interchangeable and correctly assign PE status with 80% sensitivity and 80% specificity (49). Specificity can be improved further to 96% by combining IELT with a single-item patient-reported outcome (PRO) on control over ejaculation and satisfaction with sexual intercourse (scale ranging from 0 = very poor to 4 = very good) and on personal distress and interpersonal difficulty (0 = not at all to 4 = extremely). However, stopwatch-measured IELT is necessary in clinical trials.

4.5.2 PE assessment questionnaires
The need to assess PE objectively has led to the development of several questionnaires based on the use of PROs (47). Only two questionnaires can discriminate between patients who have PE and those who do not:

- Premature Ejaculation Diagnostic Tool (PEDT: five-item questionnaire based on focus groups and interviews from the USA, Germany and Spain. Assesses control, frequency, minimal stimulation, distress and interpersonal difficulty (50,51).
- Arabic Index of Premature Ejaculation (AIPE): seven-item questionnaire developed in Saudi Arabia assesses sexual desire, hard erections for sufficient intercourse, time to ejaculation, control, satisfaction for the patient and partner, anxiety or depression (52).

These tools are a significant step in simplifying the methodology of PE drug studies, though further cross-cultural validation is needed (53).

Other questionnaires used to characterise PE and determine treatment effects include the PEP (25), Index of Premature Ejaculation (IPE), (54) and Male Sexual Health Questionnaire Ejaculatory Dysfunction (MSHQ-EjD) (55). Currently, their role is optional in everyday clinical practice.

4.5.3 Physical examination and investigations
Physical examination is part of the initial assessment of men with PE. It includes a brief examination of the vascular, endocrine and neurological systems to identify underlying medical conditions associated with PE or other sexual dysfunctions, such as chronic illness, endocrinopathy, autonomic neuropathy, Peyronie’s disease,
urethritis or prostatitis. Laboratory or physiological testing should be directed by specific findings from history or physical examination and is not routinely recommended (44).

4.8 Treatment

In many relationships, PE causes few, if any, problems. In such cases, treatment should be limited to psychosexual counselling. Before beginning treatment, it is essential to discuss patient expectations thoroughly. Erectile dysfunction, in particular, or other sexual dysfunction or genitourinary infection (e.g. prostatitis), should be treated first or at the same time as PE.

Various behavioural techniques have demonstrated benefit in treating PE and are indicated for patients uncomfortable with pharmacological therapy. In lifelong PE, behavioural techniques are not recommended for first-line treatment. They are time-intensive, require the support of a partner and can be difficult to do. In addition, long-term outcomes of behavioural techniques for PE are unknown.

Pharmacotherapy is the basis of treatment in lifelong PE. Since no drug for PE has been approved by the EMEA or FDA, all medical treatments are off-label indications. Only chronic selective serotonin reuptake inhibitors (SSRIs) and on-demand topical anaesthetic agents have consistently shown efficacy in PE. Again, long-term outcomes for pharmacological treatments are unknown.

An evidence-based analysis of all current treatment modalities was performed. Levels of evidence and grade of recommendation are provided and a treatment algorithm is presented (Figure 3).

4.8.1 Psychological/behavioural strategies

Behavioural strategies mainly include the ‘stop-start’ programme developed by Semans (1) and its modification, the ‘squeeze’ technique, proposed by Masters and Johnson.

- In the ‘stop-start’ programme, the partner stimulates the penis until the patient feels the urge to ejaculate. At this point, he instructs his partner to stop, waits for the sensation to pass and then stimulation is resumed.
- The ‘squeeze’ technique is similar but the partner applies manual pressure to the glans just before ejaculation until the patient loses his urge.

Both these procedures are typically applied in a cycle of three pauses before proceeding to orgasm. Behavioural strategies are based on the hypothesis that PE occurs because the man fails to appreciate the sensations of heightened arousal and to recognise the feelings of ejaculatory inevitability. Re-training may attenuate stimulus-response connections by gradually exposing the patient to progressively more intense and more prolonged stimulation, while maintaining the intensity and duration of the stimulus just below the threshold for triggering the response. There are several modifications of these techniques making comparison difficult.

Masturbation before anticipation of sexual intercourse is a technique used by many younger men. Following masturbation, the penis is desensitised resulting in greater ejaculatory delay after the refractory period is over. In a different approach, the man learns to recognise the signs of increased sexual arousal and how to keep his level of sexual excitement below the intensity that elicits the ejaculatory reflex. Efficacy is similar to the ‘start-stop’ programme (2).

Overall, success rates of 50-60% have been reported short term (3,4). However, there is no controlled research to support the efficacy of behavioural techniques, while a double-blind, randomised, crossover study showed that pharmacological treatment (chlomipramine, sertraline, paroxetine and sildenafil) resulted in greater
IELT prolongation than behavioural therapy (5). Furthermore, clinical experience suggests that improvements achieved with these techniques are generally not maintained long term (6,7).

4.8.1.1 Recommendation on the psychological/behavioural treatment of PE

4.8.2 Topical anaesthetic agents

The use of local anaesthetics to delay ejaculation is the oldest form of pharmacological therapy for PE (8).

4.8.2.1 Lidocaine-prilocaine cream

In a randomised, double-blind, placebo-controlled trial, lidocaine-prilocaine cream increased the IELT from 1 min in the placebo group to 6.7 min in the treatment group (11). In another randomised, double-blind, placebo-controlled trial, lidocaine-prilocaine cream significantly increased the stopwatch-measured IELT from 1.49 to 8.45 min while no difference was recorded in the placebo group (1.67 to 1.95 min) (12). Lidocaine-prilocaine cream (5%) is applied for 20 to 30 min prior to intercourse. Prolonged application of topical anaesthetic (30 to 45 min) may result in loss of erection due to numbness of the penis in a significant percentage of men (11). A condom is required to avoid diffusion of the topical anaesthetic agent into the vaginal wall causing numbness in the partner. Alternatively, the condom may be removed prior to sexual intercourse and the penis washed clean of any residual active compound. Although no significant side-effects have been reported, topical anaesthetics are contraindicated in patients or partners with an allergy to any component of the product.

An aerosol formulation of lidocaine 7.5 mg plus prilocaine 2.5 mg (Topical Eutectic Mixture for Premature Ejaculation, TEMPE (13) has been evaluated in a phase II study (14). Intravaginal ejaculatory latency time increased from a baseline of 1 min to 4.9 min in the TEMPE-treated group compared to an increase from baseline of 0.9 min to 1.6 min (p < 0.01) in the placebo-treated group. It has been suggested that lidocaine-prilocaine can penetrate the glans within 5–10 min, but penetrates intact keratinised skin less easily, reducing penile numbness and ED (14,15).

Finally, in a randomised, double-blind, placebo-controlled, parallel-group study, lidocaine-prilocaine cream showed similar efficacy to combination with sildenafil (50 mg before coitus) and significantly better efficacy than sildenafil alone (16). However, no specific data on estimated IELT were provided.

4.8.2.2 SS-cream

SS-cream is a topical anaesthetic agent made from the extracts of nine herbs. It is applied to the glans penis 1 h before and washed off immediately prior to coitus. SS-cream increased the vibratory threshold in a dose-dependent fashion, as well as the latency and amplitude of somatosensory-evoked potentials measured at the glans penis (17,18). In a double-blind, randomised, placebo-controlled study (19), application of 0.2 g SS-cream improved IELT from 1.37 min to 10.92 min in the treatment group versus 2.45 min in the placebo group. Sexual satisfaction improved by 82% in the treatment group versus 20% in the placebo group. Mild local burning and mild pain were reported by 18.5% of patients. No adverse effects on sexual function or partner or systemic side-effects were observed.

4.8.2.3 Recommendations on the topical therapy for PE

| Lidocaine-prilocaine cream. | LE | GR |
| SS-cream. | 1B | A |

4.8.3 Selective serotonin reuptake inhibitors

Ejaculation is mediated by a spinal ejaculation generator (20, 21) and by descending supraspinal modulation from several brain regions. The neurotransmitter 5-hydroxytryptamine (5-HT, serotonin) is also involved in ejaculatory control. The retarding effect of 5-HT on ejaculation is probably due to central activation (i.e. spinally and supraspinally) of 5-HT1B and 5-HT2C receptors, while stimulation of 5-HT1A receptors precipitates ejaculation.

Selective serotonin reuptake inhibitors (SSRIs) are used to treat mood disorders, but can delay
ejaculation and are therefore widely used ‘off-label’ for PE. As in depression, SSRIs must be given for 1 to 2 weeks to be effective in PE (22). Chronic SSRI administration causes prolonged increases in synaptic cleft serotonin, which desensitise the 5-HT1A and 5-HT1B receptors (23). Clomipramine, the most serotoninergic tricyclic antidepressant, was first reported in 1973 as an effective PE treatment (24). Selective serotonin reuptake inhibitors have revolutionised treatment of PE, but they have also changed our understanding of PE since the first publication on paroxetine in 1970 (25). Today, daily treatment with SSRIs has become the first choice of treatment in PE. Commonly used SSRIs include citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline, all of which have a similar pharmacological mechanism of action.

A systematic review and meta-analysis of all drug treatment studies reported that, despite methodological problems in most studies, there still remained several, well-designed, double-blind, placebo-controlled trials supporting the therapeutic effect of daily SSRIs on PE (26). Open-design studies and studies using subjective reporting or questionnaires showed greater variation in ejaculation delay than double-blind studies in which the ejaculation delay was prospectively assessed with a stopwatch.

Based on this meta-analysis, SSRIs were expected to increase the geometric mean IELT by 2.6-fold to 13.2-fold. Paroxetine was found to be superior to fluoxetine, clomipramine and sertraline. Sertraline was superior to fluoxetine, whereas the efficacy of clomipramine was not significantly different from fluoxetine and sertraline. Paroxetine was evaluated in doses of 20-40 mg, sertraline 25-200 mg, fluoxetine 10-60 mg and clomipramine 25-50 mg; there was no significant relationship between dose and response among the various drugs. There is limited evidence that citalopram may be less efficacious compared to other SSRIs, while fluvoxamine may not be effective (27,28).

 Ejaculation delay may start a few days after drug intake, but it is more evident after 1 to 2 weeks since receptor desensitisation requires time to occur. While efficacy may be maintained for several years, tachyphylaxis (decreasing response to a drug following chronic administration) may occur after 6 to 12 months (24).

Common side-effects of SSRIs include fatigue, drowsiness, yawning, nausea, vomiting, dry mouth, diarrhea and perspiration; they are usually mild and gradually improve after 2 to 3 weeks (24). Decreased libido, anorgasmia, anejaculation and ED have also been reported.

In one controlled trial, on-demand use of clomipramine (but not paroxetine), 3 to 5 h before intercourse, was reported to be efficacious, though IELT improvement was inferior compared to daily treatment with the same drug (29). However, on-demand treatment may be combined with an initial trial of daily treatment or concomitant low-dose daily treatment reducing adverse effects (30,31).

4.8.3.1 Dapoxetine

Dapoxetine is a potent SSRI, which has been designed as an on-demand oral treatment for PE. It is quickly absorbed with a Tmax of 1.5 h and is rapidly cleared, avoiding accumulation.

An integrated analysis of two, double-blind, randomised, controlled trials (1,958 patients) with dapoxetine was published (32). Dapoxetine, 30 and 60 mg, was administered 1 to 3 h before intercourse. Intravaginal ejaculatory latency time improved from a baseline of 0.9 min to 1.75 min, 2.78 min and 3.32 min in the patient groups treated with placebo, 30 mg dapoxetine, and 60 mg dapoxetine, respectively. Improved ejaculation control was reported by 51% and 58% of patients in the 30 mg and 60 mg groups, respectively. Both dapoxetine doses were effective on the first dose. Common adverse events for 30 mg and 60 mg doses of dapoxetine, respectively, were nausea (8.7%, 20.1%), diarrhea (3.9%, 6.8%), headache (5.9%, 6.8%), and dizziness (3.0%, 6.2%).

In a subanalysis of these two studies (33), 32% of men reported a two-category (from a 5-point scale, ‘very poor’ to ‘very good’) or greater increase in control and satisfaction with sexual intercourse after treatment. More than 95% of those men rated their PE as ‘slightly better’, ‘better’, or ‘much better’ on the global impression of change (7-point scale, ‘much worse’ to ‘much better’) while 67.1% gave ratings of ‘better’ or ‘much better.’ They also had greater improvements in IELT than men with less than a two-category increase in control, with a mean (SD) change from baseline of 3.7 (4.3) vs 0.77 (1.8) min, respectively. The proportions of men with a two-category or greater increase in control with dapoxetine 30 and 60 mg were 36.3% and 44.5%, respectively (vs 15% with placebo).

In another randomised, double-blind, parallel-group, placebo-controlled, phase II trial including 1,162 men in 22 countries (34), mean average IELT increased from 0.9 min at baseline (all groups) to 1.9 min, 3.2 min, and 3.5 min with placebo and dapoxetine 30 mg and dapoxetine 60 mg, respectively, at study end point. The geometric mean IELT increased from 0.7 min at baseline to 1.1 min, 1.8 min, and 2.3 min, respectively, at study end point. All PEP measures and IELTs improved significantly with dapoxetine versus placebo at week 12 and week 24 (p < 0.001 for all). The most common adverse effects were nausea, dizziness, diarrhea, and headache. Adverse effects led to discontinuation in 1.3%, 3.9%, and 8.2% of subjects with placebo and dapoxetine 30 mg. Finally, in a randomised, double-blind, placebo controlled, phase III trial (1,238 men in USA and Canada), dapoxetine reduced the personal distress and interpersonal difficulty associated with PE (35).
Dapoxetine has been approved (December 2008) for the on-demand treatment of PE in seven European countries (Sweden, Austria, Finland, Germany, Spain, Italy and Portugal). This is currently the first and only drug approved for such an indication.

### 4.8.4 Phosphodiesterase type 5 inhibitors

Several recent studies have supported the therapeutic role of PDE5 inhibitors in PE. They may reduce performance anxiety due to better erections and may down-regulate the erectile threshold to a lower level of arousal so that greater arousal is required to achieve the ejaculation threshold. However, many of the mechanisms involved remain speculative (33,36-38).

There is only one well-designed, randomised, double-blind, placebo-controlled study comparing sildenafil to placebo (39). Although IELT was not significantly improved, sildenafil increased confidence, the perception of ejaculatory control and overall sexual satisfaction, reduced anxiety and decreased the refractory time to achieve a second erection after ejaculation.

In another randomised, double-blind, placebo-controlled study, lidocaine-prilocaine had similar efficacy to combination with sildenafil (50 mg before intercourse), while the efficacy of sildenafil was similar to placebo (no IELT data provided) (16). In contrast, in a randomised, double-blind, parallel group study, sildenafil significantly improved IELT and satisfaction and reduced overall anxiety compared to several SSRIs and the ‘pause-squeeze’ technique. From a baseline of IELT at 1 min, IELT improved to 15 min with sildenafil, 4 min with clomipramine, 3 min with sertraline, 4 min with paroxetine and 3 min with the ‘pause-squeeze’ technique (5).

Finally, several open-label studies showed that sildenafil combined with an SSRI is superior to SSRI monotherapy. Sildenafil combined with paroxetine improved IELT significantly and satisfaction versus paroxetine alone (40). Sildenafil combined with sertraline improved IELT and satisfaction significantly versus sertraline alone (41). Sildenafil combined with paroxetine and psychological and behavioural counselling significantly improved IELT and satisfaction in patients in whom other treatments failed (42). Finally, sildenafil combined with behavioural therapy significantly improved IELT and satisfaction versus behavioural therapy alone (43).

There are limited data on the efficacy in PE of other PDE5 inhibitors (tadalafil and vardenafil) (37, 38). Overall, the role of PDE5 inhibitors in PE patients without ED is not established, with only minimal double-blind placebo controlled data are available.

### 4.8.4.1 Recommendation on the use of PDE5 inhibitors for the treatment of PE

### 4.8.5 Other drugs

Adrenergic blockade for PE aims to decrease the sympathetic tone of the seminal tract and therefore delay ejaculation (44). Tramadol is a centrally acting analgesic agent that combines opioid receptor activation and re-uptake inhibition of serotonin and noradrenaline.

Research suggests that the alpha-1 adrenergic antagonists, terazosin and alfuzosin (45,46), and tramadol (47,48) may have some efficacy in PE. However, further research is needed to investigate their role fully. Currently they are not recommended in clinical practice (49).

Daily SSRIs are first-line, off-label, pharmacological treatment for PE. The pharmacokinetic profile of SSRIs is not amenable to pm dosing.

Dapoxetine, a short-acting SSRI, has already been approved for the on-demand treatment of PE in seven European Countries.

Topical anaesthetic agents provide viable alternatives to SSRIs (off-label).

Recurrence is likely after treatment cessation.

Behavioural therapy may augment pharmacotherapy to enhance relapse prevention.

---

ED = erectile dysfunction; PE = premature ejaculation; SSRI = selective serotonin reuptake inhibitor; pm = on-demand administration.
Clinical diagnosis of premature ejaculation based on patient/partner history
- Time to ejaculation (IELT)
- Perceived degree of ejaculatory control
- Degree of bother/distress
- Onset and duration of PE
- Psychosocial/Relationship issues
- Medical history

Treatment of premature ejaculation
- Patient counselling
- Discussion of treatment options
- If PE is secondary to ED, treat ED first or concomitantly

Lifelong PE
- Pharmacotherapy
- Relationship counselling
- Behavioural therapy
- Combination treatment

Acquired PE
- Behavioural therapy
- Pharmacotherapy
- Relationship counselling
- Combination treatment

Attempt graduated withdrawal of Drug therapy after 6-8 weeks
- Behavioural therapy includes stop/start technique, squeeze and sensate focus
- Pharmacotherapy (off label) includes SSRIs (daily use) and topical anaesthetics; it is recommended as first-line treatment option in lifelong PE
- Consider dapoxetine for on-demand use (the only approved drug for PE)

* Adapted from Lue et al. 2004 (49).

ED = erectile dysfunction; PE = premature ejaculation; IELT = intravaginal ejaculatory latency time;
SSRI = selective serotonin receptor inhibitor.

5. CONCLUSION

Modern treatment of ED has been revolutionised by the worldwide availability of three PDE5Is for oral use – sildenafil, tadalafil and vardenafil. These drugs have high efficacy and safety rates, even in difficult-to-treat populations, such as patients with diabetes mellitus or who have undergone RP. Patients should be encouraged to try all three PDE5Is. Patients should make up their own minds about which compound has the best efficacy, while also considering other factors, such as time of onset, duration of action, window of opportunity and how side-effects affect them individually.

Treatment options for patients who do not respond to oral drugs, or for whom drugs are contraindicated, include intracavernous injections, intraurethral alprostadil, vacuum constriction devices, or implantation of a penile prosthesis.

It is very important that the physician warns the patient that sexual intercourse is a vigorous physical activity, which increases heart rate as well as cardiac work. Physicians should assess the cardiac fitness of patients prior to treating ED.

Any successful pharmacological treatment for erectile failure demands a degree of integrity of the penile mechanisms of erection. Further studies of individual agents and synergistic activity of available substances are underway. The search for the ideal pharmacological therapy for erectile failure aims to fulfill the following characteristics: good efficacy, easy administration, freedom from toxicity and side-effects, with a rapid onset and a possible long-acting effect.

Premature ejaculation is another very common male sexual dysfunction, with prevalence rates of 20% to 30%. Four major definitions of PE are currently used and the most widely accepted classification of PE includes “lifelong” (primary) and “acquired” (secondary) forms (syndromes).

Diagnosis of PE in everyday clinical practice is based on medical and sexual history assessing IELT, perceived control, distress, and interpersonal difficulty related to the ejaculatory dysfunction. Physical examination and laboratory testing may be needed in selected patients only.

Pharmacotherapy is the basis of treatment in lifelong PE including daily dosing of SSRIs and topical anaesthetics. Behavioural techniques may be efficacious as a monotherapy or in combination with pharmacotherapy, but they can be difficult to perform. In every case, recurrence is likely to occur after treatment withdrawal.

1. INTRODUCTION

Penile curvature can be congenital or acquired. Congenital curvature is discussed in these guidelines as a distinct pathology in the adult population without any other concomitant abnormality present (such as urethral abnormalities). For paediatric congenital penile curvature, please refer to the EAU Guidelines on Paediatric Urology, Chapter 7, Congenital Penile Curvature.

Acquired curvature is secondary due to La Peyronie’s disease (referred to as Peyronie’s disease in this text), which was named by a French physician, François Gigot de La Peyronie, in 1743 - although he was not the first one to describe this disease (1).

2. METHODOLOGY

A systematic literature search of the Medline database was performed by panel members. The controlled vocabulary of the Medical Subject Headings (MeSH) database uses the specific term ‘penile induration’ for Peyronie’s disease. There is no specific MeSH term for congenital penile curvature. In order to identify relevant articles, the search included the MeSH terms ‘congenital abnormalities’, ‘penis/*abnormalities’ and ‘male’ as well as the free text term ‘congenital penile curvature’. Since this is the first time guidelines on this topic are published, the search includes all relevant articles published up to January 2012. A total of 48 articles were identified for congenital penile curvature while this number was 1200 for Peyronie’s disease. The panel reviewed all these records and selected the articles with the highest evidence available. However, in several subtopics only articles with low levels of evidence were available and discussed accordingly.

2.1 Level of evidence and grade of recommendation

The level of evidence (LE) and grade of recommendation (GR) provided in these guidelines follow the listings in Tables 1 and 2. The aim of grading the recommendations is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

*Modified from Sackett et al. (2).

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and the grade of recommendation. The availability of RCTs may not necessarily translate into a grade A recommendation if there are methodological limitations or disparities in the published results. Conversely, an absence of high-level evidence does not necessarily preclude a grade A recommendation if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the reader. Whenever this occurs, it has been clearly indicated in the text with an asterisk as ‘upgraded based on panel consensus’. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned (3-5).

The EAU Guidelines Office does not perform cost assessments, nor can they address local/national preferences in a systematic fashion. However, whenever such data are available, the expert panels will include the information.

2.2 Publication history
The present Penile Curvature guidelines are a new publication that underwent a blinded peer-review process before publication. The standard procedure will be an annual assessment of newly published literature in this field, guiding future updates. An ultra-short reference document is being published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

3. CONGENITAL PENILE CURVATURE

3.1 Epidemiology and physiopathology
Congenital curvature is rare: one study reports an incidence of less than 1% (6) while another suggests it is more common with prevalence rates of 4-10% in the absence of hypospadias (7).

There is no evident cause of congenital penile curvature. A single study analysing the ultrastructure of the tunica albuginea has demonstrated widening and fragmentation of collagen fibres, with complete disappearance of striation and transformation into electron-dense, fibrous, granulated material and elastin accumulation (8).

3.2 Patient evaluation
Taking medical and sexual history are usually sufficient to establish the diagnosis of congenital penile curvature. Physical examination during erection is only useful to document curvature and exclude other pathologies (9). Erectile function is normal but it can be compromised by excessive curvature.

3.3 Treatment
Only androgens have been tried for congenital penile curvature with no improvement in adults (10). Therefore, the treatment of this pathology is only surgical. Surgical treatments for congenital penile curvature generally share the same principles as in Peyronie's disease (presented in detail in the next section) but can be performed at any time in adults. Notably, most operations for Peyronie's disease have been described first for congenital penile curvature (11). Plication techniques are used almost exclusively with high curvature correction rates (67-97%) (12-14). The use of grafting material in isolated congenital penile curvature is too limited to draw any meaningful conclusions (15).

4. PEYRONIE’S DISEASE

4.1 Epidemiology, physiopathology and natural history

Epidemiological data on Peyronie’s disease are limited. Prevalence rates of 0.4-9% have been published (16-22).

The aetiology of Peyronie’s disease is unknown. However, an insult (repetitive microvascular injury or trauma) to the tunica albuginea is the most widely accepted hypothesis on the aetiology of the disease (23). Peyronie’s disease starts with an acute inflammatory process. The acute inflammation is characterised by increased proliferation of the tunical fibroblasts, some of which differentiate into myofibroblasts, with excessive deposition of collagen, persistence of fibrin and elastin fragmentation. A prolonged inflammatory response will result in the remodelling of connective tissue into a dense fibrotic plaque (23-25). Penile plaque formation can result in curvature which, if severe, may prevent vaginal intromission. The most commonly associated comorbidities and risk factors are diabetes, hypertension, lipid abnormalities, ischaemic cardiopathy, erectile dysfunction, smoking, and excessive consumption of alcohol (21,22,26,27). Dupuytren’s contracture is more common in patients with Peyronie’s disease affecting 9-39% of patients (18,28-30) while 4% of patients with Dupuytren’s contracture reported Peyronie’s disease (28). However, it is still unclear if these factors contribute to the pathophysiology of Peyronie’s disease. While the pathogenesis has to be clarified, younger men and Caucasian men are at increased risk for Peyronie’s disease after radical pelvic surgery, e.g. radical prostatectomy (31).

Peyronie’s disease can be a chronic and progressive disease. Two phases of the disease can be distinguished (32). The first is the acute inflammatory phase, which may be associated with pain in the flaccid state or painful erections and manifestation of a ‘soft’ nodule/plaque and penile curvature. The second is the fibrotic phase with the formation of hard palpable plaques that can be calcified, which also result in disease stabilisation. With time, penile curvature is expected to worsen in 30-50% of patients or stabilise in 47-67% of patients, while spontaneous improvement has been reported by only 3-13% of patients (27,33,34). An improvement in penile curvature is more likely to occur in the early stage of the disease, rather than in a later phase when the plaque has been formed and has become densely calcified (35). Pain is present in 35-45% of patients during the early stages of the disease (36). Pain tends to resolve with time in 90% of men, usually during the first 12 months after the onset of the disease (33,34).

In addition to physiological and functional alteration of the penis, affected men also suffer significant distress. Validated mental health questionnaires have shown that 48% of men with Peyronie’s disease have mild or moderate depression, sufficient to warrant medical evaluation (37).

4.2 Patient evaluation

The aim of the initial evaluation is to provide information on the presenting symptoms and their duration (erectile pain, palpable nodules, curvature, length, rigidity, and girth) and erectile function status. It is mandatory to obtain information on the distress provoked by the symptoms and the potential risk factors for erectile dysfunction and Peyronie’s disease. Although a disease-specific questionnaire has been designed to collect data, it is yet a validated instrument suitable for use in clinical practice (38).

Major attention should be given to whether the disease is still active, as this will influence medical treatment or the timing of surgery. Patients who are still likely to have an active disease are those with short symptom
duration, pain during erection, or a recent change in penile curvature. It is often difficult to evaluate the end of the inflammatory phase, but resolution of pain and stability of the curvature for at least 3 months are well-accepted criteria of disease stabilisation and patients referral for surgical intervention when indicated (see Section 4.4.4 Surgical treatment of penile curvature) (33).

The examination should start with a routine genitourinary assessment, which is then extended to the hands and feet for detecting possible Dupuytren’s contracture or Ledderhose scarring of the plantar fascia (34). Penile examination consists generally of a palpable node or plaque. The whole of the penis should be examined. There is currently no standardised approach, but it is recommended to measure the penis dorsally from the base to the tip of the glans while at full stretch (34). Plaque size is measured in the erect penis. However, there is no correlation between plaque size and the degree of curvature (35). Measurement of length during erection is important because it impacts directly on treatment decisions (39). Girth-related changes are often self-reported by the patients.

Erectile function can be assessed using validated instruments such as the International Index of Erectile Function (IIEF) (40). However, it should be noted that IIEF has not been validated specifically in Peyronie’s disease patients. Erectile dysfunction is quite common (> 50%) in patients with Peyronie’s disease but it is important to define if pre-dated or post-dated Peyronie’s disease onset. It is mainly due to penile vascular disease (27,35). The presence of erectile dysfunction may impact on the treatment strategy (41).

Ultrasound (US) measurement of the plaque’s size is inaccurate and operator dependent and it is not recommended in everyday clinical practice (42). Doppler US may be required for the assessment of vascular parameters (41) (see also Section 2.5.3.3 and Table 3 in the EAU Guidelines on Male Sexual Dysfunction). An objective assessment of penile curvature with an erection is mandatory. This can be obtained by a home (self) photograph of a natural erection (preferably) or using a vacuum-assisted erection test or an intracavernosal injection using vasoactive agents (38).

### 4.3 Non-operative treatment

Conservative treatment of Peyronie’s disease is primarily focused on patients in the early stage of the disease, when symptoms are present and the plaque is not densely fibrotic or calcified (34,43). In this context, several options have been suggested, including oral pharmacotherapy, intralesion injection therapy and other topical treatments, which will be discussed in this section (Table 1). The role of conservative treatment in men with stable/chronic disease has not yet been adequately defined (32,44). No single drug has been approved by the European Medical Association for the treatment of Peyronie’s disease. Only potassium para-aminobenzoate (Potaba) has been classified as ‘possibly effective’ by the Food and Drug Administration (FDA) for the treatment of Peyronie’s disease.

The results of the studies on conservative treatment for Peyronie’s disease are often contradictory making it difficult to provide recommendations in the everyday, real-life setting. This fact is due to several methodological problems including uncontrolled studies, limited number of patients treated, short term follow-up and different outcome measures (44). Moreover, the efficacy of conservative treatment in distinct patient population in terms of early (inflammatory) or late (fibrotic) phases of the disease is not yet available.

4.3.1 Oral treatment

4.3.1.1 Vitamin E
Vitamin E (tocopherol, a fat-soluble compound that acts as a natural antioxidant to reduce the number of oxygen-free radicals produced in energy metabolism) is commonly prescribed by the majority of urologists at once or twice daily doses of 400 IU because of its wide availability, low cost and safety (45). Despite the fact that it has been suggested as a potential treatment option in patients with Peyronie’s disease (46), a double-blind, placebo-controlled crossover study failed to show a significant effect on penile deformity or plaque size (47).

4.3.1.2 Potassium para-aminobenzoate (Potaba)
Potassium para-aminobenzoate is thought to exert an antifibrotic effect through an increase in oxygen uptake by the tissues, a rise in the secretion of glycosaminoglycans, and an enhancement of the activity of monoamine oxidases (48). Its role in the treatment of Peyronie’s disease is due to preliminary studies that reported an improvement in penile curvature, penile plaque size, and penile pain during erection (49). In a prospective double-blinded controlled study in 41 patients with Peyronie’s disease, potassium para-aminobenzoate (12 g/day for 12 months) improved penile pain significantly, but not penile curvature or penile plaque size (50). In another prospective, randomised, double-blind, placebo-controlled in 103 patients with Peyronie’s disease, potassium para-aminobenzoate (4 x 3 g/day for 12 months) decreased penile plaque size significantly, but had no effect on penile curvature or penile pain (51). However, the pre-existing curvature under potassium para-aminobenzoate remained stable, suggesting a protective effect on the deterioration of penile curvature. Treatment-emergent adverse events are nausea, anorexia, pruritus, anxiety, chills, cold sweats, confusion and difficulty in concentration, but no serious adverse events were reported.

4.3.1.3 Tamoxifen
Tamoxifen is a non-steroidal oestrogen receptor antagonist. Its proposed mechanism of action in Peyronie’s disease involves the modulation of TGFβ1 secretion by fibroblasts. Preliminary studies reported that tamoxifen (20 mg twice daily for 3 months) improved penile pain, penile curvature, and reduced the size of penile plaque (52). However, a placebo-controlled, randomised study (in only 25 patients, at late stage of the disease with a mean duration of 20 months) using the same treatment protocol, failed to show any significant improvement in pain, curvature, or plaque size in patients with Peyronie’s disease (53).

4.3.1.4 Colchicine
Colchicine is a medicine often used to treat acute attacks of gout. It has been introduced into the treatment
of Peyronie’s disease on the basis of its anti-inflammatory effect (54). Preliminary results in 24 men showed that half of the men given colchicine (0.6-1.2 mg daily for 3-5 months) found that painful erections and penile curvature improved, while penile plaque decreased or disappeared in 50% (55). In another study in 60 men (colchicine 0.5-1 mg daily for 3-5 months with escalation to 2 mg twice daily), penile pain resolved in 95% and penile curvature improved in 30% (54). Similar results have been reported in another uncontrolled retrospective study in 118 patients. The study concluded that lateral curvature is the most commonly altered deformity, which mostly shifts to the dorsal side of the penis after colchicine therapy (56). Reported treatment-emergent adverse events with colchicine are gastrointestinal effects (nausea, vomiting, diarrhoea) that can be improved with dose escalation (54).

The combination of vitamin E and colchicine (600 mg/day and 1 mg every 12 hours, respectively) for 6 months in patients with early-stage Peyronie’s disease resulted in significant improvement in plaque size and curvature, but not in pain compared to ibuprofen 400 mg/day for 6 months (57).

4.3.1.5 Acetyl esters of carnitine

Although the actual mechanism of action of acetyl esters of carnitine in patients with Peyronie’s disease is unknown, it has been suggested that it can reduce intracellular calcium levels in endothelial cells (58). This may eventually suppress fibroblast proliferation and collagen production, thus reducing penile fibrosis. In a randomised, double-blind study in 48 patients with early-stage Peyronie’s disease, patients were randomised to acetyl-L-carnitine (1 g twice daily) compared to tamoxifen (20 mg twice daily). After 3 months, acetyl-L-carnitine was significantly more effective than tamoxifen in pain and curvature reduction and in inhibiting disease progression but not in penile plaque size reduction (both drugs significantly reduced plaque size) (59). Tamoxifen induced significantly more side-effects.

Finally, the combination of intralesional verapamil (10 mg weekly for 10 weeks) with propionyl-l-carnitine (2 g/day for 3 months) significantly reduced penile curvature, plaque size, and disease progression compared to intralesional verapamil combined with tamoxifen (40 mg/day) for 3 months (60).

4.3.1.6 Pentoxifylline

Pentoxifylline is a non-specific phosphodiesterase inhibitor which down regulates TGFβ1 and increases fibrinolytic activity (61). Moreover, an increase of nitric oxide levels may be effective in preventing progression of Peyronie’s disease or reversing fibrosis (62). Preliminary data from a case report showed that pentoxifylline (400 mg three times daily for 6 months) improved penile curvature and the findings on US of the plaque (62). In another study in 62 patients with Peyronie’s disease, pentoxifylline treatment for 6 months appeared to stabilise or reduce calcium content in penile plaques (63).

4.3.1.7 Phosphodiesterase type 5 inhibitors

The rationale for the use of phosphodiesterase type 5 inhibitors (PDE5I) in Peyronie’s disease comes from animal studies showing that they can reduce the collagen/smooth muscle and collagen III/I ratios and increase the apoptotic index in the Peyronie’s disease-like plaque (64). In a retrospective controlled study, daily tadalafil (2.5 mg for 6 months) resulted in statistically significant (p < 0.05) resolution of septal scar in 69% of patients compared to 10% in the control group (no treatment). However, this study included patients with isolated septal scars without evidence of penile deformity (65). Therefore, no recommendation can be given for PDE5I in patients with Peyronie’s disease.

4.3.2 Intralesional treatment

Injection of pharmacologically active agents directly into penile plaques represents another treatment option. It allows a localised delivery of a particular agent that provides higher concentrations of the drug inside the plaque. However, delivery of the compound to the target area is difficult to ensure.

4.3.2.1 Steroids

Intralesional steroids are thought to act by opposing the inflammatory milieu responsible for Peyronie’s plaque progression via inhibition of phospholipase A2, suppression of the immune response and by decreasing collagen synthesis (66). In small, non-randomised studies, a decrease in penile plaque size and pain resolution was reported (67,68). In the only single-blind, placebo-controlled study with intralesional administration of betamethasone, no statistical significant changes in penile deformity, penile plaque size, and penile pain during erection were reported (69). Adverse effects include tissue atrophy, thinning of the skin and immune suppression (67).
4.3.2.2  Verapamil
The rationale for intralesional use of verapamil (a calcium channel antagonist) in patients with Peyronie’s disease is based on in-vitro data that demonstrated transport of extracellular matrix molecules, which included collagen, fibronectin, and glycosaminoglycans as a calcium-dependent process, along with a concomitant increase in collagenase activity, a modification of the inflammatory response in the early phase of the disorder, and the inhibition of fibroblast proliferation in the plaques (70,71). A number of studies have reported that intralesional verapamil injection may induce a significant reduction in penile curvature and plaque volume (72-76). These findings suggested that intralesional verapamil injections (multiple-puncture technique, 10 mg of verapamil diluted to 10 mL, distributed throughout the plaque every 2 weeks for a total of 12 consecutive sessions) could be advocated for the treatment of non-calcified acute phase or chronic plaques to stabilise disease progression or possibly reduce penile deformity, although large scale, placebo-controlled trials have not yet been conducted (72). Side effects are uncommon (4%). Minor side effects include nausea, light-headedness, penile pain, and ecchymosis (72). However, in the only randomised, placebo-controlled study, no statistical significant differences on plaque size, penile curvature, penile pain during erection or plaque ‘softening’ were reported (77). Younger age and larger baseline penile curvature were found to be predictive of favourable curvature outcomes in a case-series study (78).

4.3.2.3  Clostridial collagenase
Clostridial collagenase is a chromatographically purified bacterial enzyme that selectively attacks collagen, which is known to be the primary component of the Peyronie’s disease plaque (79-81). Conversely, clostridial collagenase injections received FDA approval for Dupuytren’s contracture, with a similar mechanism of action (82). In a prospective randomised, placebo-controlled, double-blind study, comparing the effects on plaque size and penile deformity of intralesional purified clostridial collagenase (6,000-14,000 units) and saline placebo, the overall response was 36% while in the placebo arm it was 4% (p < 0.007) (79). Follow-up was only 3 months. The response rates were even higher in patients with smaller plaques and curvature less than 60°. The efficacy of intralesional collagenase injections (three injections of clostridial collagenase 10,000 unit/0.25 cm3 per injection administered over 7-10 days and subsequently administered over 7-10 days at 3 months) has been assessed over a non-placebo-controlled, short-term follow-up study conducted in a small population of men with Peyronie’s disease (81). Although methodologically-biased, this study showed significant decreases from baseline in the deviation angle, in plaque width and in plaque length. The most commonly reported side effects were penile pain, contusions, and ecchymosis.

4.3.2.4  Interferon
Interferon α-2b has been shown to decrease fibroblast proliferation, extracellular matrix production and collagen production from fibroblasts and improved the wound healing process from Peyronie’s disease plaques in-vitro (83). Intralesional injections (5 x 106 units of interferon α-2b in 10 mL saline, two times per week for 12 weeks) significantly improved penile curvature, plaque size and density, and pain compared to placebo (84,85). Side effects include myalgias, arthralgia, sinusitis, fever and flu-like symptoms. They can be effectively treated with non-steroidal anti-inflammatory drugs before interferon injection.

4.3.3  Topical treatments
4.3.3.1  Topical verapamil
In a small, randomised, placebo-controlled study, topical verapamil (gel 15% applied topically to the penile shaft twice daily) significantly improved penile curvature, plaque size, and penile pain (86). Moreover, treatment results significantly improved after 9 months compared to 3 months, showing that a prolonged treatment period may be important. However, there is lack of evidence that topical verapamil applied to the penile shaft results in adequate levels of the active compound within the tunica albuginea (87).

4.3.3.2  Iontophoresis
Iontophoresis (also known as transdermal electromotive drug administration or electromotive drug administration [EMDA]) has been introduced to try and overcome limitations on the local uptake of the drugs themselves. Uncontrolled studies showed promising results in terms of improvement in penile curvature, plaque size and penile pain during erection (88-90). In a randomised, double-blind, controlled study, iontophoresis with verapamil 5 mg and dexamethasone 8 mg resulted in a statistically significant improvement in penile curvature and plaque size (91). However, in another randomised, double-blind, placebo-controlled study, penile curvature was not statistically improved after iontophoresis with verapamil 10 mg (92). The method is not associated with any significant adverse event.

4.3.3.3  Extracorporeal shock wave lithotripsy
The mechanism of action involved in shock wave lithotripsy (SWL) for Peyronie’s disease is still unclear,
but there are two hypotheses. In the first hypothesis, shock wave therapy works by directly damaging and remodelling the penile plaque. In the second hypothesis, SWL increases the vascularity of the area by generating heat resulting in an inflammatory reaction, with increased macrophage activity causing plaque lysis and eventually leading to plaque resorption (93). Most uncontrolled studies failed to show significant improvements in patients with Peyronie’s disease (94-96). In a prospective, randomised, double-blind, placebo-controlled study, four weekly treatment sessions of SWL, with each session consisting of 2000 focused shock waves, resulted in significant improvement only for penile pain (97).

4.3.3.4 Traction devices
The application of continuous traction in Dupuytren’s contracture increases the activity of degradative enzymes (98). This initially leads to a loss of tensile strength and ultimately to solubilisation. It is followed by an increase in newly synthesised collagen (98). This concept has been applied in an uncontrolled study, including 10 patients with Peyronie’s disease (the FastSize Penile Extender was applied as the only treatment for 2-8 hours/day for 6 months) (99). Penile curvature reduced in all men from 10° to 45°, with an average reduction of 33% (range: 51-34°). The stretched penile length increased to 0.5-2.0 cm. The erect girth increased to 0.5-1.0 cm, with a correction of hinge effect in four out of four men. There were no adverse events, including skin changes, ulcerations, hypoesthesia or diminished rigidity.

However, in another uncontrolled study in 15 patients with Peyronie’s disease and a curvature of less than 50° (the Andropenis Penile Extender was applied for at least 5 hours per day for 6 months). The decrease in penile curvature was minimal (4°, the effect size was not reached), while the mean stretched and flaccid penile length increased by 1.3 and 0.83 cm, respectively, at 6 months (100).

4.3.3.5 Vacuum devices
The application of vacuum devices follows the same principles as traction devices. Their efficacy has been assessed in an uncontrolled study (31 patients completed the study) (101). They used a vacuum device for 10 min twice daily over a 12 week period. Penile pain reduced significantly (p = 0.012). Stretched penile length also increased significantly (p = 0.029) with a mean of 0.5 cm. Reduction of the curvature was reported in 67% of patients while 10% of them had a worsening and 23% had no change. Half of them were satisfied with the outcome and the remaining had their curvature corrected surgically.

4.4 Surgical treatment
Although conservative treatment for Peyronie’s disease should resolve painful erections in most men, only a small percentage will experience any significant straightening of the penis. The aim of surgery is to correct curvature and allow satisfactory intercourse (102). Surgery is indicated only in patients with stable disease for at least 3 months, although a 6-12 month period has also been suggested (103).

The potential aims and risks of surgery should be discussed with the patient so that he can make an informed decision. Specific issues that should be mentioned during this discussion are the risks of penile shortening, erectile dysfunction, penile numbness, the risk of recurrent curvature, the potential for palpation of knots and stitches underneath the skin, and the potential need for circumcision at the time of surgery (32).

Two major types of repair may be considered for both congenital penile curvature and Peyronie’s disease: penile shortening and penile lengthening procedures (104). Penile shortening procedures include the Nesbit wedge resection and the plication techniques performed on the convex side of the penis. Penile lengthening procedures are performed on the concave side of the penis and require the use of a graft. They aim to minimise penile shortening caused by Nesbit or plication of the tunica albuginea or correct complex deformities. Penile degloving with associated circumcision (as a means of preventing post-operative phimosis) is considered the standard approach for all types of procedures (104). However, recent data suggest that circumcision is not always necessary. In cases where the foreskin is normal pre-operatively, circumcision is unnecessary (105). Finally, in patients with Peyronie’s disease and erectile dysfunction not responding to medical treatments, the surgical correction of the curvature with concomitant penile prosthesis implantation should be considered (106).

Choosing the most appropriate surgical intervention is based on penile length assessment, curvature severity and erectile function status, including response to pharmacotherapy in cases of erectile dysfunction (32). Patient expectations from surgery must also be included in the pre-operative assessment. There are no standardised questionnaires for the evaluation of surgical outcomes (102). Data from well-designed prospective studies are scarce, with a low level of evidence. Most data are mainly based on retrospective studies, typically non-comparative and non-randomised, or on expert opinion (32,107).

4.4.1 Penile shortening procedures
In 1965, Nesbit was the first to describe the removal of tunical ellipses opposite a non-elastic corporal segment to treat congenital penile curvature (11). Fourteen years later, this technique became a successful treatment option, also for Peyronie’s disease (108). This operation is based on a 5-10 mm transverse elliptical excision of the tunica albuginea or approximately 1 mm for each 10° of curvature (104). The overall short- and long-term results of the Nesbit operation are excellent. Complete penile straightening is achieved in more than 80% of patients (109). Recurrence of the curvature and penile hypoesthesia are uncommon (about 10%) and the risk of postoperative erectile dysfunction is minimal (104,110). Penile shortening is the most commonly reported outcome of the Nesbit procedure (110). However, shortening of only 1-1.5 cm has been reported for about 85% of patients, which is rarely the cause for post-operative sexual dysfunction (108,111). Patients often perceive the loss of length as greater than it actually is (109,110). It is therefore advisable to measure and document the penile length peri-operatively, both before and after the straightening procedure, whatever the technique used. Only one modification of the Nesbit procedure has been described (partial thickness shaving instead of conventional excision of a wedge of tunica albuginea) (112).

Plication procedures actually share the same principle as the Nesbit operation but are simpler to perform. Many of them have been described as Nesbit modifications in the older literature. They are based on single or multiple longitudinal incisions on the convex side of the penis closed in a horizontal way, applying the Heineke-Miculicz principle, or plication is performed without making an incision (113-118). Another modification has been described as the ‘16 dot’ technique with minimal tension under local anaesthesia (119). The use of non-absorbable sutures reduced recurrence of the curvature. Results and satisfaction rates are similar to the Nesbit procedure (104). However, a lot of different modifications have been described and the level of evidence is not sufficient to recommend one method over the other.

4.4.2 Penile lengthening procedures
Tunical lengthening procedures entail an incision in the short (concave) side of the tunica to increase the length of this side, creating a tunical defect, which is covered by a graft. However, plaque removal may be associated with high rates of postoperative erectile dysfunction due to venous leak (120).

Devine and Horton introduced dermal grafting in 1974 (121). Since then, a variety of grafting materials and
techniques have been reported (Table 2) (122-136). Unfortunately, the ideal material for grafting has yet to be identified. In addition, grafting procedures are associated with erectile dysfunction rates as high as 25%. Despite excellent initial surgical results, graft contracture and long-term failures resulted in a 17% re-operation rate (137).

Vein grafts have the theoretical advantage of endothelial-to-endothelial contact when grafted to underlying cavernosal tissue. Saphenous vein is the most common vein graft used, followed by dorsal penile vein (104). In the latter case, a secondary incision for graft harvesting is avoided. Postoperative curvature (20%), penile shortening (17%) and graft herniation (5%) have been reported after vein graft surgery (122-124). Tunica vaginalis is relatively avascular, easy to harvest and has little tendency to contract due to its low metabolic requirements (126).

Dermal grafts are commonly associated with contracture resulting in recurrent penile curvature (35%), progressive shortening (40%), and a 17% re-operation rate at 10 years (138). Cadaveric pericardium (Tutoplast®) offers good results by coupling excellent tensile strength and multi-directional elasticity/expansion by 30% (129). In a retrospective telephone interview, 44% of patients with pericardium grafting reported recurrent curvature, although most of them continued to have successful intercourse and were pleased with their outcomes (129,138).

Small intestinal submucosa (SIS, a collagen-based xenogenic graft derived from the submucosal layer of the porcine small intestine) has been shown to promote tissue-specific regeneration, and supports the growth of endothelial cells. Small intestinal submucosa acts as a scaffold to promote angiogenesis, host cell migration and differentiation, resulting in tissue structurally and functionally similar to the original. It has been used successfully to repair severe chordee and Peyronie’s disease, without significant contraction or histological alterations, but data are limited (133).

Tunical incision, preferably with grafting, offers an excellent surgical option for men with curvatures over 60º as well as patients with an hourglass deformity and good erectile function that are willing to risk a higher rate of postoperative erectile dysfunction (139). The presence of pre-operative erectile dysfunction, the use of larger grafts, age more than 60 years, and ventral curvature are considered poor prognostic factors for functional outcome after grafting surgery (106). Although the risk for penile shortening is significantly less compared to the Nesbit or plication procedures, it is still an issue and patients must be informed accordingly (104). The use of a penile extender device on an 8- to 12-hour daily regimen has been advocated as an effective and safe way to the loss of penile length in patients operated on for Peyronie’s disease (140).

### 4.4.3 Penile prosthesis

Penile prosthesis implantation is typically reserved for the treatment of Peyronie's disease in patients with erectile dysfunction, especially when they are not responders to phosphodiesterase type 5 inhibitor (PDE5I) (104). Although all types of penile prosthesis can be used, the implantation of inflatable penile prosthesis seems to be most effective in these patients (141).

Most patients with mild-to-moderate curvature can expect an excellent outcome simply by cylinder insertion. In cases of severe deformity, intra-operative ‘modelling’ of the penis over the inflated cylinders (manually bent on the opposite side of the curvature for 90 seconds, often accompanied by an audible crack) has been introduced as an effective treatment (142,143). If there is a residual curvature of less than 30º, no further treatment is recommended, as the prosthesis will act as a tissue expander and will result in complete correction of curvature in a few months (142). While this technique is effective in most patients, a Nesbit/plication procedure or plaque excision/incision and grafting may be required in order to achieve adequate straightening (144-146).

The risk of complications (infection, malformation, etc.) is not increased compared to the general population. However, a small risk of urethral perforation (3%) has been reported in patients with ‘modelling’ over the inflated prosthesis (143).

#### 4.4.4 Treatment algorithm

The decision on the most appropriate surgical procedure to correct penile curvature is based on pre-operative assessment of penile length, the degree of the curvature and erectile function status. If the degree of curvature is less than 60º, penile shortening is acceptable and the Nesbit or plication procedures are usually the method of choice. This is typically the case for congenital penile curvature. If the degree of curvature is over 60º or is a complex curvature, or if the penis is significantly shortened in patients with a good erectile function (with or without pharmacological treatment), then a grafting procedure is feasible. If there is erectile dysfunction, which is not responding to pharmacological treatment, the best option is the implantation of an inflatable penile prosthesis, with or without an associated procedure over the penis (modelling, plication or even grafting plus the prosthesis). The treatment algorithm is presented in Figure 1.
The results of the different surgical approaches are presented in Table 3. It must be emphasised that there are no randomised controlled trials available addressing surgery in Peyronie’s disease. The risk of erectile dysfunction seems to be greater for penile lengthening procedures (32,104). Recurrent curvature implies either failure to wait until the disease has stabilised, a reactivation of the condition following the development of stable disease, or the use of re-absorbable sutures that lose their strength before fibrosis has resulted in acceptable strength of the repair (104). Accordingly, it is recommended that only non-absorbable sutures or slowly reabsorbed absorbable sutures be used. Although with non-absorbable sutures, the knot should be buried to avoid troublesome irritation of the penile skin, this issue seems to be alleviated by the use of slowly re-absorbed absorbable sutures (110). Penile numbness is a potential risk of any surgical procedure involving mobilisation of the dorsal neurovascular bundle. This will usually be a neuropraxia, due to bruising of the dorsal sensory nerves. Given that the usual deformity is a dorsal deformity, the procedure most likely to induce this complication is a lengthening (grafting) procedure for a dorsal deformity (104).

**ED = erectile dysfunction.**
8. Surgery is indicated when Peyronie’s disease is stable for at least 3 months (without pain or deformity deterioration), which is usually the case after 12 months from the onset of symptoms, and intercourse is compromised due to deformity.

9. Penile length, curvature severity, erectile function (including response to pharmacotherapy in case of erectile dysfunction) and patient expectations must be assessed prior to surgery.

10. Tunical shortening procedures, especially plication techniques are the first treatment options for congenital penile curvature and for Peyronie’s disease with adequate penile length, curvature < 60° and absence of special deformities (hour-glass, hinge).

11. Grafting techniques are the preferred treatment option for patients with Peyronie’s disease with no adequate penile length, curvature > 60° and presence of special deformities (hour-glass, hinge).

12. Penile prosthesis implantation, with or without any additional procedure (modelling, plication or grafting), is recommended in Peyronie’s disease patients with erectile dysfunction not responding to pharmacotherapy.

1. METHODOLOGY

1.1 Introduction
The European Association of Urology (EAU) Guidelines Panel on Male Infertility has prepared these guidelines to assist urologists and healthcare professionals from related specialties in the treatment of male infertility.

Urologists are usually the specialists who are initially responsible for assessing the male partner when male infertility is suspected. However, infertility can be a multifactorial condition requiring multidisciplinary involvement. The Male Infertility Guidelines Panel consists of urologists, endocrinologists and gynaecologists with special training in andrology and experience in the diagnosis and treatment of male infertility.

1.2 Data identification
The recommendations provided in the current guidelines are based on a systemic literature search performed by the panel members. MedLine, Embase, and Cochrane databases were searched to identify original and review articles. The controlled vocabulary of the MeSH database was used alongside a free-text protocol, combining “male infertility” with the terms “diagnosis”, “epidemiology”, “investigations”, “treatment”, “spermatogenic failure”, “genetic abnormalities”, “obstruction”, “hypogonadism”, “varicocele”, “cryptorchidism”, “testicular cancer”, “male accessory gland infection”, “idiopathic”, “contraception”, “ejaculatory dysfunction”, and “cryopreservation”.

All articles published between January 2011 (previous update) and October 2012 were considered for review. The expert panel reviewed these records and selected articles with the highest evidence.

1.3 Level of evidence and grade of recommendation
References in the text have been assessed according to their level of scientific evidence (Table 1), and guideline recommendations have been graded (Table 2) according to the Oxford Centre for Evidence-based Medicine Levels of Evidence (1). Grading aims to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

</tr>
</tbody>
</table>

*Modified from (1).

It should be noted that when recommendations are graded, the link between the level of evidence (LE) and grade of recommendation (GR) is not directly linear. Availability of randomised controlled trials (RCTs) may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Alternatively, absence of high level of evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. There may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful. Whenever this occurs, it is indicated in the text as “upgraded based on panel consensus”. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences, and costs when a grade is assigned (2-4).

The EAU Guidelines Office does not perform structured cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever these data are available, the expert panel will include the information.

1.4  Publication history

The EAU Male Infertility Guidelines were first published in 2001, followed by full-text updates in 2004, 2007, 2010 and 2012. For this 2013 publication, all sections have been revised and limited changes implemented. Starting in 2012, the expert panel instigated a new updating cycle. A quick reference guide presenting the main findings of the Male Infertility Guidelines is also available (Pocket Guidelines), as well as a number of scientific publications in the EAU journal European Urology (5-7). The Male Infertility panel published a separate scientific paper on Vasectomy in 2012 (7). All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/online-guidelines/.

1.5  Potential conflict of interest statement

The expert panel have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guidelines/.

1.6  Definition

“Infertility is the inability of a sexually active, non-contracepting couple to achieve spontaneous pregnancy in one year”, World Health Organization (WHO) (8).

1.7  Epidemiology and aetiology

About 15% of couples do not achieve pregnancy within one year and seek medical treatment for infertility. One in eight couples encounter problems when attempting to conceive a first child and one in six when attempting to conceive a subsequent child. Three percent of women remain involuntarily childless, while 6% of parous women are not able to have as many children as they would wish (9). Infertility affects both men and women. In 50% of involuntarily childless couples, a male-infertility-associated factor is found together with abnormal semen parameters. A fertile partner may compensate for the fertility problem of the man and thus infertility usually becomes manifest if both partners have reduced fertility (8). Male fertility can be reduced as a result of (8):

- congenital or acquired urogenital abnormalities;
- malignancies;
- urogenital tract infections;
- increased scrotal temperature (e.g. as a consequence of varicocele);
- endocrine disturbances;
- genetic abnormalities;
- immunological factors.

In 30-40% of cases, no male-infertility-associated factor is found (idiopathic male infertility). These men present with no previous history of diseases affecting fertility and have normal findings on physical examination and endocrine laboratory testing. However, semen analysis reveals a decreased number of spermatozoa (oligozoospermia), decreased sperm motility (asthenozoospermia), and many abnormal forms of sperm (teratozoospermia). These sperm abnormalities usually occur together and are called oligo-asthenoteratozoospermia (OAT) syndrome.

Table 3 summarises the main male-infertility-associated factors. Idiopathic male infertility is assumed to be caused by several factors, including endocrine disruption as a result of environmental pollution, reactive oxygen species, or genetic and epigenetic abnormalities.

1.8 Prognostic factors

Prognostic factors for male infertility are:
- duration of infertility;
- primary or secondary infertility;
- results of semen analysis and
- age and fertility status of female partner.

The cumulative pregnancy rate is 27% in infertile couples with 2 years of follow-up and oligozoospermia as the primary cause of infertility (11). Female age is the most important single variable influencing outcome in assisted reproduction (12). Compared to a woman aged 25 years, the fertility potential of a woman aged 35 years is reduced to 50%, to 25% at 38 years, and less than 5% at over 40 years. In many Western countries, women postpone their first pregnancy until after their education and starting a career.

2. INVESTIGATIONS

2.1 Semen analysis

A medical history and physical examination are standard assessments in all men, including semen analysis. A comprehensive andrological examination is indicated if semen analysis shows abnormalities compared with reference values (Table 4). Important treatment decisions are based on the results of semen analysis, therefore, it is essential that the complete laboratory work-up is standardised. Ejaculate analysis has been standardised by the WHO and disseminated by publication of the WHO Laboratory Manual for the Examination and Processing of Human Semen (5th edn.) (1). It is the consensus that modern spermatology must follow these guidelines.

2.1.1 Frequency of semen analysis

If the results of semen analysis are normal according to WHO criteria, one test is sufficient. If the results are abnormal in at least two tests, further andrological investigation is indicated. It is important to differentiate between the following:

- **oligozoospermia**: spermatozoa < 15 million/mL;
- **asthenozoospermia**: < 32% motile spermatozoa;
- **teratozoospermia**: < 4% normal forms.

Often, all three anomalies occur simultaneously, which is defined as OAT syndrome. As in azoospermia, in extreme cases of oligozoospermia (spermatozoa < 1 million/mL), there is an increased incidence of obstruction of the male genital tract and genetic abnormalities.

3. TESTICULAR DEFICIENCY (PRIMARY SPERMATOGENIC FAILURE)

3.1 Definition
Testicular deficiency as a consequence of primary spermatogenic failure is caused by conditions other than hypothalamic-pituitary disease and obstruction of the male genital tract. It is the commonest form of reduced male fertility. Testicular deficiency may have different aetiologies and present clinically as severe OAT or non-obstructive azoospermia (NOA) (1).

3.2 Aetiology
The causes of testicular deficiency are summarised in Table 5.

3.3 Medical history and physical examination
Typical findings from the history and physical examination of a patient with testicular deficiency are:
- cryptorchidism;
- testicular torsion;
- genitourinary infection;
- testicular trauma;
- exposure to environmental toxins;
- gonadotoxic medication including anabolic drugs;
- exposure to radiation or cytotoxic agents;
- testicular cancer;
- absence of testes;
- abnormal secondary sexual characteristics;
- gynaecomastia;
- abnormal testicular volume and/or consistency;
- varicocele.

3.4 Investigations
Routine investigations include semen analysis and hormonal determinations. Other investigations may be required depending on the individual situation.

3.4.1 Semen analysis
In NOA, semen analysis shows normal ejaculate volume and azoospermia after centrifugation. A recommended method is semen centrifugation at 3000 g for 15 min and a thorough microscopic examination by phase contrast optics at ×200 magnification of the pellet. All samples can be stained and re-examined microscopically (2).

3.4.2 Hormonal determinations
In men with testicular deficiency, hypergonadotrophic hypogonadism is usually present, with high levels of follicle-stimulating hormone (FSH) and luteinising hormone (LH), and sometimes low levels of testosterone.
Generally, the levels of FSH correlate with the number of spermatogonia:
- when spermatogonia are absent or markedly diminished, FSH values are usually elevated;
- when the number of spermatogonia is normal, but maturation arrest exists at the spermatocyte or spermatid level, FSH values are within the normal range.

However, for an individual patient, FSH levels do not accurately predict the spermatogenesis status (3-5).

### Testicular biopsy

Testicular biopsy can be part of intracytoplasmic sperm injection (ICSI) treatment in patients with clinical evidence of NOA. Testicular sperm extraction (TESE) is the technique of choice and shows excellent repeatability (6-8). Spermatogenesis may be focal, which means that in about 50% of men with NOA, spermatozoa can be found and used for ICSI. Most authors therefore recommend taking several testicular samples (9,10). There is a good correlation between the histology found upon diagnostic biopsy and the likelihood of finding mature sperm cells during testicular sperm retrieval and ICSI (7,11,12). However no threshold value has been found for FSH, inhibin B, or testicular volume and successful sperm harvesting. When there are complete AZFa and AZFb microdeletions, the likelihood of sperm retrieval is almost zero.

Microsurgical TESE may increase retrieval rates versus conventional TESE, even though comparative studies are not yet available (13-15). After opening the testis, an enlarged tubule is excised using microscissors or forceps. Then, tubules are minced using mechanical or enzymatic digestion to facilitate sperm search (16). Positive retrievals are reported even in conditions such as Sertoli cell only syndrome type II (1). Percutaneous epididymal sperm aspiration (PESA) results in lower retrieval rates than microsurgical TESE and does not allow histological examination to detect carcinoma in situ (CIS) and testicular malignancies (17,18). PESA may also result in more tubular and vascular damage than TESE (19).

The results of ICSI are worse when using sperm retrieved from men with NOA compared to sperm from ejaculated semen and from men with obstructive azoospermia (OA) (20-24). Birth rates are lower in NOA versus OA (19% vs 28%) (25).
- ICSI results in significantly lower fertilisation and implantation rates (26).
- Miscarriage rates are higher in NOA versus OA (11.5% vs 2.5%) (27).
- Neonatal health in terms of birth parameters, major anomalies and chromosomal aberrations in a large cohort of children born after use of non-ejaculated sperm are comparable to the outcome of children born after use of ejaculated sperm (28).

In OA, there were no significant differences in ICSI results between testicular and epididymal sperm (23). Also, no significant differences have been reported in ICSI results between the use of fresh and frozen-thawed sperm (23,25,26).

4. GENETIC DISORDERS IN INFERTILITY

4.1 Introduction
All urologists working in andrology must have an understanding of genetic abnormalities associated with infertility, so that they can provide correct advice to couples seeking fertility treatment. Men with very low sperm counts can be offered a reasonable chance of paternity, using in vitro fertilisation (IVF), ICSI, and sperm harvesting from the epididymis or the testes in case of azoospermia. However, the spermatozoa of infertile men show an increased rate of aneuploidy, structural chromosomal abnormalities, and DNA damage, carrying the risk of passing genetic abnormalities to the next generation. Current routine clinical practice is based on the screening of genomic DNA from peripheral blood samples, however, screening of chromosomal anomalies in spermatozoa is also feasible and can be performed in selected cases (1,2).

4.2 Chromosomal abnormalities
Chromosome abnormalities can be numerical (e.g. trisomy) or structural (e.g. inversions or translocations) (3). In a survey of pooled data from 11 publications, including 9,766 infertile men, the incidence of chromosomal abnormalities was 5.8% (3). Of these, sex chromosome abnormalities accounted for 4.2% and autosomal abnormalities for 1.5%. In comparison, the incidence of abnormalities was 0.38% in pooled data from three series, with a total of 94,465 newborn male infants, of which 131 (0.14%) were sex chromosome abnormalities and 232 (0.25%) autosomal abnormalities (3). The frequency of chromosomal abnormalities increases as testicular deficiency becomes more severe. Patients with a spermatozoa count < 5 million/mL already show
Based on the frequencies of chromosomal aberrations in patients with different sperm concentration, karyotype analysis is indicated in men with azoospermia or oligozoospermia (spermatozoa < 10 million/mL) (5,7). If there is a family history of recurrent spontaneous abortions, malformations or mental retardation, karyotype analysis should be requested, regardless of the sperm concentration.

4.2.1 Sex chromosome abnormalities (Klinefelter’s syndrome and variants [47,XXY; 46,XY/47, XXY mosaicism])
Klinefelter’s syndrome is the most common sex chromosome abnormality (3,8). Adult men with Klinefelter’s syndrome have small firm testicles, devoid of germ cells. The phenotype varies from a normally virilised man to one with the stigmata of androgen deficiency, including female hair distribution, scant body hair, and long arms and legs due to late epiphyseal closure. Leydig cell function is commonly impaired in men with Klinefelter’s syndrome (9). Testosterone levels may be normal or low, oestradiol levels normal or elevated, and FSH levels increased. Libido is often normal despite low testosterone levels, but androgen replacement may be needed as the patient ages.

Germ cell presence and sperm production are variable in men with Klinefelter’s mosaicism, 46,XY/47,XXY. There is one case report of declining spermatogenesis in a man with Klinefelter’s syndrome, with the recommendation that early sperm retrieval should be considered (10). Based on sperm fluorescence in situ hybridisation (FISH) studies showing an increased frequency of sex chromosomal abnormalities and increased incidence of autosomal aneuploidy (disomy for chromosomes 13, 18 and 21), concerns have been raised about the chromosomal normality of the embryos generated through ICSI (11).

The production of 24,XY sperm has been reported in 0.9% and 7.0% of men with Klinefelter’s mosaicism (12,13) and in 1.36-25% of men with somatic karyotype 47,XXY (14-17). In patients with azoospermia, TESE or (micro-TESE) can be proposed as a therapeutic option since spermatozoa can be recovered in about 30% of cases. To date, 49 healthy children have been born using ICSI without preimplantation genetic diagnosis (PGD) and the conception of one 47,XXY foetus has been reported (8). However, a study of ICSI combined with PGD in 113 embryos reported a significant fall in the rate of normal embryos for couples with Klinefelter’s syndrome with respect to controls (54% vs 77.2%) (15). Due to the significant increase of sex chromosomal and autosomal abnormalities in the embryos of Klinefelter’s patients, PGD or amniocentesis analysis should be considered.

Follow-up (possibly every year) of men with Klinefelter’s syndrome is required and androgen replacement therapy should be started when testosterone level is in the range of hypoandrogenism.

4.2.2 Autosomal abnormalities
Genetic counselling should be offered to all couples seeking fertility treatment (including IVF/ICSI) when the male partner is known or found to have an autosomal karyotype abnormality.

The most common autosomal karyotype abnormalities are Robertsonian translocations, reciprocal translocations, paracentric inversions, and marker chromosomes. It is important to look for these structural chromosomal anomalies because there is an increased associated risk of aneuploidy or unbalanced chromosomal complements in the foetus. As with Klinefelter’s syndrome, sperm FISH analysis provide a more accurate risk estimation of affected offspring, however, the diffusion of this genetic test is largely limited by the availability of laboratories able to perform this analysis.

When IVF/ICSI is carried out for men with translocations, PGD or amniocentesis should be performed. Embryos with known unbalanced translocation should not be implanted.

4.2.3 Sperm chromosomal abnormalities
Sperm can be examined for their chromosomal constitution using multicolour FISH both in men with normal karyotype and with anomalies. Aneuploidy in sperm, particularly sex chromosome aneuploidy, is associated with severe damage to spermatogenesis (3,18-20) and with translocations (21).

Florescence in situ hybridisation analysis of spermatozoa remains a research investigation, although it has been proposed for clinical use to assess spermatozoa from men with defined andrological conditions (18). Techniques are needed to separate populations of genetically abnormal sperm from normal sperm or to safely screen individual spermatozoa before IVF and ICSI.

4.3 Genetic defects
4.3.1 X-linked genetic disorders and male fertility
Each man has only one X-chromosome. An X-linked recessive disorder manifests in males. The defect will be transmitted to daughters, but not to sons.
4.3.2 **Kallmann syndrome**
The most common X-linked disorder in infertility practice is Kallmann syndrome due to mutation in the KALIG-1 gene on Xp22.3 (22). Several newly identified autosomal gene mutations can also cause Kallmann syndrome (23). Patients with Kallmann syndrome have hypogonadotrophic hypogonadism and anosmia, but may also have other clinical features, including facial asymmetry, cleft palate, colour blindness, deafness, maldescended testes, and unilateral renal aplasia.

Spermatogenesis can be relatively easily induced by hormonal treatment (24), therefore, genetic screening prior to therapy is advisable although it is limited by the rarity of specialised genetic laboratories that can offer this genetic test. Treatment with gonadotropins allows natural conception in most cases, even for men with a relatively low sperm count. Thus, identification of the involved gene (X-linked, autosomal dominant or recessive) can help to provide more accurate genetic counselling, that is, risk estimation for transmission to the offspring.

4.3.3 **Mild androgen insensitivity syndrome**
The AR gene is located on the long arm of the X-chromosome. Mutations in the AR gene may result in mild to complete androgen insensitivity (25). The phenotypic features of complete androgen insensitivity syndrome are female external genitalia and absence of pubic hair (Morris syndrome). In partial androgen insensitivity syndrome, several different phenotypes are evident, ranging from predominantly female phenotype through ambiguous genitalia, to predominantly male phenotype with micropenis, perineal hypospadias, and cryptorchidism. The latter phenotype is also termed Reifenstein syndrome. In the above-mentioned severe forms of androgen resistance, there is no risk of transmission because affected men cannot generate their own biological children using the current technologies. Patients with mild androgen insensitivity syndrome have male infertility as their primary or even sole symptom. Disorders of the androgen receptor causing infertility in the absence of any genital abnormality are rare, and only a few mutations have been reported in infertile (26-29) or fertile (30) men.

4.3.4 **Other X-disorders**
An unexpectedly high number of genes with a testis-specific or enriched expression pattern have been identified on the X-chromosome, and in particular, premeiotic genes are over-represented on the X-chromosome compared with autosomal chromosomes (31,32). Nevertheless, to date only a few genes have been screened in relatively small populations and none of them appear relevant for male infertility (33,34). Two recent independent studies showed a significantly higher deletion load on the X-chromosome in men with spermatogenic failure with respect to normozoospermic controls (35,36).

4.4 **Y-chromosome and male infertility**

4.4.1 **Introduction**
The first association between azoospermia and microscopically detectable deletions of the long arm of the Y-chromosome was demonstrated in 1976 (37). With the advent of molecular genetic tools, microdeletions have been defined in three non-overlapping regions termed AZFa, AZFb and AZFc (38). With knowledge of the precise structure of the Y-chromosome in Yq11, it subsequently became clear that the AZFb and AZFc regions overlap and that there is no AZFd region (39). Clinically relevant deletions remove partially, or in most cases completely, one or more of the AZF regions, and are the most frequent molecular genetic cause of severe oligozoospermia and azoospermia (40). In each AFZ region, there are several spermatogenesis candidate genes (41). Deletions occur en bloc (i.e. removing more than one gene), thus, it is not possible to determine the role of a single AZF gene from the AZF deletion phenotype and it is unclear if they all participate in spermatogenesis. Gene-specific deletions, which remove a single gene, have been reported only in the AZFa region and concern the USP9Y gene. These studies have suggested that USP9Y is most likely to be a “fine tuner” of sperm production, and its specific screening is not advised (42).

4.4.2 **Clinical implications of Y microdeletions**
The clinical significance of Yq microdeletions can be summarised as follows:

- They are not found in normozoospermic men, proving there is a clear cut cause-and-effect relationship between Y-deletions and spermatogenic failure (43).
- The highest frequency of Y-deletions is found in azoospermic men (8-12%), followed by oligozoospermic (3-7%) men.
- Deletions are extremely rare with a sperm concentration > 5 million/mL (~0.7%).
- AZFc deletions are most common (65-70%), followed by deletions of the AZFb and AZFb+c or AZFa+b+c regions (25-30%). AZFa region deletions are rare (5%).
- Complete removal of the AZFa region is associated with severe testicular phenotype (Sertoli cell only syndrome), while complete removal of the AZFb region is associated with spermatogenic rest.
Complete removal of the AZFc region causes a variable phenotype ranging from azoospermia to oligozoospermia.

- Classical (complete) AZF deletions do not confer a risk for cryptorchidism or testicular cancer (40).

The specificity and genotype/phenotype correlation reported above means that Y deletion analysis has both a diagnostic and prognostic value for testicular sperm retrieval (40).

4.4.2.1 Testing for Y microdeletions

Indications for AZF deletion screening are based on sperm count and include azoospermia and severe oligozoospermia (spermatozoa count $< 5 \text{ million/mL}$). Thanks to the European Academy of Andrology (EAA) guidelines (44) and EAA/EMQN (European Molecular Genetics Quality Network) external quality control programme (http://www.emqn.org/emqn/), Yq testing has become more homogeneous and reliable in different routine genetic laboratories. The EAA guidelines provide a set of primers capable of detecting $> 95\%$ of clinically relevant deletions (44). The primers consist of two markers for each region and control markers from the Yp and X-chromosomes. The initial reports of large variability of deletion frequencies are more likely to have been caused by technical problems and unreliable markers rather than be an expression of true ethnic differences.

4.4.2.2 Genetic counselling for AZF deletions

After conception, any Y-deletions are transmitted obligatorily to the male offspring, and genetic counselling is therefore mandatory. In most cases, father and son have the same microdeletion (45-48), but occasionally the son has a larger one (49). The extent of spermatogenic failure (still in the range of azoo-/oligozoospermia) cannot be predicted entirely in the son, due to the different genetic background and the presence or absence of environmental factors with potential toxicity for reproductive function. A significant proportion of spermatozoa from men with complete AZFc deletion are nullisomic for sex chromosomes (50,51), indicating a potential risk for any offspring to develop 45,X0 Turner’s syndrome and other phenotypic anomalies associated with sex chromosome mosaicism, including ambiguous genitalia. The screening for Y-chromosome microdeletions in patients bearing a mosaic 46,XY/45,X0 karyotype with sexual ambiguity and/or Turner stigmata has shown a relatively high incidence of AZFc deletions (33%) (52). There are data to support the association of Yq microdeletions with an overall Y-chromosomal instability, which leads to the formation of 45,X0 cell lines (53,54). Despite this theoretical risk, babies born from fathers affected by Yq microdeletions are phenotypically normal (40,44). This could be due to the reduced implantation rate and a likely higher risk of spontaneous abortion of embryos bearing a 45,X0 karyotype.

When ICSI is used in the presence of a Y microdeletion, long-term follow up of any male children is needed with respect to their fertility status and cryopreservation of spermatozoa at a young age can be considered.

4.4.2.3 Y-chromosome: ‘gr/gr’ deletion

A new type of Yq deletion, known as the gr/gr deletion, has been described in the AZFc region (55). This deletion removes half of the gene content of the AZFc region, affecting the dosage of multicopy genes mapping inside this region. There was an almost eightfold higher risk of developing oligozoospermia [odds ratio (OR) = 7.9, 95\% confidence interval (CI): 1.8-33.8; \( P < 0.001 \)] in gr/gr deletion carriers in the largest Caucasian study population published to date (56). The frequency of gr/gr deletion in oligozoospermic patients is $\sim 4\%$. According to four meta-analyses, gr/gr deletion is a significant risk factor for impaired sperm production (57,58).

However, it is worth noticing that both the frequency of gr/gr deletion and its phenotypic expression vary between different ethnic groups, depending on the Y-chromosome background. For example, in some Y haplogroups, the deletion is fixed and appears to have no negative effect on spermatogenesis. Consequently, the routine screening for gr/gr deletion is a still a debated issue, especially in those laboratories serving diverse ethnic and geographic populations. A large multicentre study has shown that gr/gr deletion is a potential risk factor for testicular germ cell tumours (59). However, these data need further confirmation in an ethnically and geographically matched case-control study setting. For genetic counselling it is worth noticing that partial AZFc deletions (gr/gr and b2/b3) may predispose to complete AZFc deletion in the next generation (60).
4.4.2.4 Conclusions and recommendations

**Conclusions**

<table>

</table>

**4.4.3 Autosomal defects with severe phenotypic abnormalities and infertility**

Several inherited disorders are associated with severe or considerable generalised abnormalities and infertility (Table 6). Patients with these defects will be well known to doctors, often from childhood. A fertility problem must be managed in the context of the care of the man as a whole and considering the couple’s ability to care for a child.

**4.5 Cystic fibrosis mutations and male infertility**

Cystic fibrosis (CF) is a fatal autosomal-recessive disorder. It is the most common genetic disease of Caucasians; 4% are carriers of gene mutations involving the CF transmembrane conductance regulator (CFTR) gene located on chromosome 7p. It encodes a membrane protein that functions as an ion channel and influences the formation of the ejaculatory duct, seminal vesicle, vas deferens and distal two-thirds of the epididymis.

Congenital bilateral absence of the vas deferens (CBAVD) is associated with CFTR gene mutations and was found in ~2% of men with OA attending a clinic in Edinburgh, UK (61). The incidence in men with OA varies between different countries. The clinical diagnosis of absent vasa is easy to miss and all men with azoospermia should be very carefully examined to exclude CBAVD; particularly those with a semen volume < 1.5 mL and pH < 7.0. Approximately 1,500 mutations are listed on the CFTR database (http://www.genet.sickkids.on.ca/cftr/). Many studies have been published of men with CBAVD tested for varying numbers of
mutations. The most frequently found mutations are the ΔF508, R117H and W1282X but their frequency and the presence of other mutations largely depend on the ethnicity of the patient (62,63). Given the functional relevance of a DNA variant (the 5T allele) in a non-coding region of CFTR (63), it is now considered a mild CFTR mutation rather than a polymorphism and it should be analysed in each CAVD patient.

As more mutations are defined and tested for, almost all men with CBAVD will probably be found to have mutations. It is not practical to test for all known mutations, because many have a very low prevalence in a particular population. Routine testing is usually restricted to the most common mutations in a particular community.

Given that this is a recessive disease, mutations should be found on both alleles of the CFTR gene; however, with the routine panel, in most men with CBAVD, mutation is found in only one copy. In these cases a second step analysis is advised which comprises the direct sequencing of the entire gene. Men with CBAVD often have mild clinical stigmata of CF (e.g., history of chest infections).

When a man has CBAVD, it is important to test him and his partner for CF mutations. If the female partner is found to be a carrier of CFTR mutations, the couple must consider very carefully whether to proceed with ICSI using the husband’s sperm, as the risk of a having a child with CF or CBAVD will be 50%, depending on the type of mutations carried by the parents. If the female partner is negative for known mutations, the risk of being a carrier of unknown mutations is ~0.4%.

4.6  Unilateral or bilateral absence/abnormality of the vas and renal anomalies
Unilateral absence of the vas deferens is usually associated with ipsilateral absence of the kidney and probably has a different genetic causation (64). Consequently, in these subjects CFTR mutation screening is not indicated. Men with unilateral absence of the vas deferens are usually fertile, and the condition is most commonly encountered as an incidental finding in the vasectomy clinic. CFTR gene mutation screening is indicated in men with unilateral absence of the vas deferens with normal kidneys.

An abdominal ultrasound should be undertaken both in unilateral and bilateral absence of vas deferens. Findings may range from unilateral absence of the vas with ipsilateral absence of the kidney, to bilateral vessel abnormalities and renal abnormalities, such as pelvic kidney (65).

4.7  Unknown genetic disorders
Considering the high predicted number of genes involved in male gametogenesis, it is likely that most idiopathic forms of spermatogenic disturbances are caused by mutations or polymorphisms in spermatogenesis candidate genes (34). However, despite an intensive search for new genetic factors, no clinically relevant gene mutations or polymorphisms (except those related to the Y-chromosome) have so far been identified (34, 66, 67, and references therein). The introduction of new analytical approaches is likely to provide major advances in this field (68,69).

Intracytoplasmic sperm injection is used to enable men with severely damaged spermatogenesis to father children in situations formerly considered hopeless and where very few spermatozoa can be obtained. This has led to concern that children may be born with a foetal abnormality, because ICSI may enable defective sperm to bypass the selective processes of the female genital tract and egg covering. Alternatively, eggs may be fertilised that would otherwise not be.

Intracytoplasmic sperm injection babies have a higher risk of de novo sex chromosomal aberrations (about a threefold increase compared with natural conceptions) and paternally inherited structural abnormalities. Treatment with assisted reproductive technology was associated with increased risks of cardiovascular, musculoskeletal, urogenital, and gastrointestinal defects and cerebral palsy (70-72).

4.8  DNA fragmentation in spermatozoa
There is increased DNA damage in spermatozoa from men with oligozoospermia. This increase is associated with reduced chances of natural conception and an increase of early pregnancy loss (73,74). DNA damage may improve after varicocele ligation (75,76).

4.9  Genetic counselling and ICSI
The best management is to agree treatment with the couple and provide them with full information on the genetic risks. Initially, the couple should be given full information about the risks to the child to help them decide whether to proceed with ICSI. Where there is conflict between the wishes of the couple and the interests of the future child, it may be ethically correct to withhold therapy.

When both partners are known to carry defects (e.g., CFTR mutations), there is up to a 50% chance of the child developing a clinical condition. Many clinicians and infertility clinic personnel may consider it unethical to proceed because their duty of care to the future child and the interests of society outweigh the wishes of the individual couple. If there is a conflict that cannot be resolved by agreement, the interests of a future child probably take precedence over the interests of a couple. The couple also need to give
consideration to preimplantation diagnosis and replacement only of normal embryos.

5. **OBSTRUCTIVE AZOOSPERMIA**

5.1 **Definition**
Obstructive azoospermia OA is the absence of spermatozoa and spermatogenetic cells in semen and post-ejaculate urine due to bilateral obstruction of the seminal ducts. OA is less common than NOA and occurs in 15-20% of men with azoospermia. Common causes of OA are summarised in Table 7.

Men with OA present with normal FSH, normal size testes, and epididymal enlargement. Sometimes, the vas deferens is absent due to congenital factors or previous inguinal or scrotal surgery. Obstruction in primary infertile men is often present at the epididymal level; other sites of obstruction are the ejaculatory ducts and the vas deferens. In 25% of men with a suspected obstruction, no spermatozoa are found in the epididymis during scrotal exploration, indicating an intratesticular obstruction or non-obstructive cause.

5.2 Classification

5.2.1 Intratesticular obstruction
Intratesticular obstruction occurs in 15% of men with OA (1). Congenital forms (dysjunction between rete testis and efferent ductules) are less common than acquired forms, that is, post-inflammatory or post-traumatic obstructions. Acquired forms are often associated with an obstruction of the epididymis and vas deferens.

5.2.2 Epididymal obstruction
Epididymal obstruction or disjunction is the most common cause of OA, affecting 30-67% of azoospermic men with serum FSH level less than twice the upper limit of normal (1-4).

Congenital epididymal obstruction usually manifests as CBAVD, which is associated with at least one mutation of the CF gene in 82% of cases (5). This form is often accompanied by absence of the distal part of the epididymis and seminal vesicle agenesis (see Chapter 4). Other congenital forms of obstruction are rare, for example, disjunction between efferent ductules and the corpus epididymis; agenesis/atrophy of a short part of the epididymis.

Congenital forms of epididymal obstruction include chronic sinopulmonary infections (Young’s syndrome) (6), in which obstruction results from a mechanical blockage due to debris within the proximal epididymal lumen.

Acquired forms secondary to acute (e.g., gonococcal) and subclinical (e.g., chlamydial) epididymitis are most common (7,8) (see Chapter 11). Acute or chronic traumas can result in epididymal damage (9).

Azoospermia caused by surgery may occur after epididymal surgery, for example, cyst removal. Epididymal obstruction secondary to long-lasting distal obstruction must be considered when repairing seminal ducts (10).

5.2.3 Vas deferens obstruction
Vas deferens obstruction is the most common cause of acquired obstruction following vasectomy for sterilisation, with possible subsequent germ cell impairment and fibrosis (11,12). Approximately 2-6% of these men request vasectomy reversal. Of those undergoing vasovasostomy, 5-10% have epididymal blockage as a result of tubule rupture, making epididymovasostomy mandatory (see Chapter 10). Vasal obstruction may also occur after herniotomy (13). Polypropylene mesh herniorrhaphy appears to be able to induce a fibroblastic response that can entrap or obliterate the vas deferens (14).

The most common congenital vasal obstruction is CBAVD, often accompanied by CF. Unilateral agenesis or a partial defect is associated with contralateral seminal duct anomalies or renal agenesis in 80% and 26% of cases, respectively (15) (see Chapter 4). Distal vas deferens obstruction includes CBAVD and accidental injury to the vas deferens during hernia surgery (16).

5.2.4 Ejaculatory duct obstruction
Ejaculatory duct obstruction is found in 1-3% of cases of OA (1) and is classified as either cystic or post-inflammatory.

Cystic obstructions are usually congenital (i.e., Mullerian duct cyst or urogenital sinus/ejaculatory duct cysts) and are medially located in the prostate between the ejaculatory ducts. In urogenital sinus abnormalities, one or both ejaculatory ducts empty into the cyst (17), while in Mullerian duct anomalies, the ejaculatory ducts are laterally displaced and compressed by the cyst (18).

Paramedian or lateral intraprostatic cysts are Wolffian in origin and rare in clinical practice (19).

Post-inflammatory obstructions of the ejaculatory duct are usually secondary to acute, non-acute, or chronic urethroprostatitis (20).

Congenital or acquired complete obstructions of the ejaculatory ducts are commonly associated with low semen volume, decreased or absent seminal fructose, and acid pH. The seminal vesicles are usually dilated (anterior-posterior diameter > 15 mm) (20,21).

5.2.5 Functional obstruction of the distal seminal ducts
Functional obstruction of the distal seminal ducts might be attributed to local neuropathy (22). This abnormality is often associated with urodynamic dysfunction because of the vasographic patterns of ampullo-vesicular atony or ejaculatory duct hypertony. Functional obstruction of the distal seminal ducts has been reported in juvenile diabetes and polycystic kidney disease (23); however, no relevant pathology has been found in most cases. Results of semen analysis vary between azoospermia, cryptozoospermia and severe OAT syndrome.

5.3 Diagnosis

5.3.1 Clinical history
Clinical history taking should follow the suggestions for investigation of infertile men (see Chapter 2).
Patients should be asked about:
- haematospermia;
- post-ejaculatory pain;
- previous or present urethritis or prostatitis;
- obstructive or irritative urinary symptoms;
- previous scrotal enlargement or pain or surgery;
- previous inguinal herniorrhaphy or trauma;
- chronic sinopulmonary infection.

5.3.2 Clinical examination
Clinical examination should follow suggestions for investigation of infertile men. The following findings indicate OA:
- at least one testis with a volume > 15 mL, although a smaller volume may be found in some patients with OA and concomitant partial testicular failure;
- enlarged and hardened epididymis;
- nodules in the epididymis or vas deferens;
- absence or partial atresia of the vas;
- signs of urethritis;
- prostatic abnormalities.

5.3.3 Semen analysis
At least two examinations must be carried out at an interval of 2-3 months, according to the WHO (see Chapter 2). Azoospermia means the inability to detect spermatozoa after centrifugation at ×400 magnification. Careful repeat observation of several smears after semen liquefaction is needed. If no spermatozoa are found in a wet preparation, then aliquots or the whole semen sample should be centrifuged at 3,000 g for 15 min. The pellet must be examined for spermatozoa.

Ejaculatory duct obstruction or CBAVD is suggested by a semen volume < 1.5 mL, acid pH, and low fructose level. When semen volume is low, a search must be made for spermatozoa in urine after ejaculation, because their presence confirms an ejaculatory disorder. Absence of spermatozoa and immature germ cells in semen smears suggest complete proximal or distal seminal duct obstruction.

5.3.4 Hormone levels
Serum FSH levels may be normal, but do not exclude a testicular cause of azoospermia (e.g., spermatogenic arrest). FSH level is normal in 40% of men with primary spermatogenic failure. Inhibin B seems to have a higher predictive value for normal spermatogenesis (4).

5.3.5 Ultrasonography
Scrotal ultrasound is helpful in finding signs of obstruction (e.g., dilatation of rete testis, enlarged epididymis with cystic lesions, or absent vas deferens) and may demonstrate signs of testicular dysgenesis (e.g., non-homogeneous testicular architecture and microcalcifications) and associated CIS of the testis. For patients with a low seminal volume and in whom distal obstruction is suspected, transrectal ultrasound (TRUS) is essential. If possible, TRUS should be performed at high resolution and with high-frequency (> 7 MHz) biplane transducers. Seminal vesicle enlargement (anteroposterior diameter 15 mm) (21) and round, anechoic areas in the seminal vesicle (24) are TRUS anomalies more often associated with ejaculatory duct obstruction; especially when semen volume is < 1.5 mL. Mullerian duct or urogenital sinus/ejaculatory duct cysts (20) and ejaculatory duct calcifications (25) are other known anomalies in OA. TRUS may also be used to aspirate seminal vesicle fluid (26).

Invasive diagnosis, including testicular biopsy, scrotal exploration, and distal seminal duct evaluation, are indicated in patients with OA in whom an acquired obstruction of the seminal ducts is suspected. Explorative and recanalisation surgery should be carried out simultaneously.

5.3.6 Testicular biopsy
In selected cases, testicular biopsy may be indicated to exclude spermatogenic failure. Testicular biopsy should be combined with extraction of testicular spermatozoa (i.e., TESE) for cryopreservation and subsequent ICSI, when surgical recanalisation cannot be carried out or has failed. A scoring system for testicular biopsies is provided (e.g., Johnsen Score) (27).

5.4 Treatment
5.4.1 Intratesticular obstruction
Intratesticularly, seminal duct recanalisation is impossible. TESE allows sperm retrieval in nearly all OA patients.
and is therefore recommended. The spermatozoa retrieved may be used immediately for ICSI or should be cryopreserved.

5.4.2 **Epididymal obstruction**
Microsurgical epididymal sperm aspiration (MESA) (28) is indicated in men with CBAVD. TESE and PESA are also viable options for retrieving epididymal sperm from men with OA (29). Retrieved spermatozoa are used for ICSI. Usually, one MESA procedure provides sufficient material for several ICSI cycles (30) and it produces high pregnancy and fertilisation rates (31). In patients with azoospermia due to acquired epididymal obstruction, end-to-end or end-to-side microsurgical epididymovasostomy is recommended, with the preferred technique being microsurgical intussusception epididymovasostomy (32).

Reconstruction may be carried out unilaterally or bilaterally; patency and pregnancy rates are usually higher with bilateral reconstruction. Before microsurgery, it is important to check for full patency downstream of the epididymis. Anatomical recanalisation following surgery may require 3-18 months. Before microsurgery (and in all cases where recanalisation is impossible), epididymal spermatozoa should be aspirated and cryopreserved for use in ICSI in case of surgical failure (30).

Patency rates range between 60% and 87% (33-35) and cumulative pregnancy rates between 10% and 43%. Recanalisation success rates may be adversely affected by preoperative and intra-operative findings (e.g., concomitant abnormal testicular histology, absence of sperm in the spermatic fluid on sectioning the small epididymal tubules, or extensive fibrosis of the epididymis).

5.4.3 **Proximal vas obstruction**
Proximal vas obstruction after vasectomy requires microsurgical vasoepididymostomy (see Chapter 10). Vasoepididymostomy is also required in rare cases of proximal vasal obstructions (e.g., iatrogenic, post-traumatic, or post-inflammatory). The absence of spermatozoa in the intraoperative vas deferens fluid suggests the presence of a secondary epididymal obstruction; especially if the seminal fluid of the proximal vas has a thick “toothpaste” appearance. Microsurgical tubulovasostomy is then indicated.

5.4.4 **Distal vas deferens obstruction**
It is usually impossible to correct large bilateral vas deferens defects, resulting from involuntary excision of the vasa deferentia during hernia surgery in early childhood or previous orchidopexy (16). In these cases, proximal vas deferens sperm aspiration (37) or TESE/MESA can be used for cryopreservation for future ICSI. In large unilateral vas deferens defects associated with contralateral testicular atrophy, the vas deferens of the atrophic testis can be used for a crossover vasoepididymostomy or tubulovasostomy.

5.4.5 **Ejaculatory duct obstruction**
The treatment of ejaculatory duct obstruction depends on its aetiology. Transurethral resection of the ejaculatory ducts (TURED) (20,38) can be used in large post-inflammatory obstruction and when one or both ejaculatory ducts empty into an intraprostatic midline cyst. Resection may remove part of the verumontanum.

In cases of obstruction due to a midline intraprostatic cyst, incision or unroofing of the cyst is required (20). Intraoperative TRUS makes this procedure safer. If distal seminal tract evaluation is carried out at the time of the procedure, installation of methylene blue dye into the vas deferens can help to document opening of the ducts. The limited success rate of surgical treatment of ejaculatory duct obstruction in terms of spontaneous pregnancies should be weighed against sperm aspiration and ICSI.

Complications following TURED include retrograde ejaculation due to bladder neck injury and urine reflux into the ejaculatory ducts, seminal vesicles, and vasa (causing poor sperm motility, semen acid pH, and epididymitis). The alternatives to TURED are MESA, TESE, proximal vas deferens sperm aspiration, seminal vesicle ultrasonically guided aspiration, and direct cyst aspiration.

In cases of functional obstruction of the distal seminal ducts, TURED often fails to improve sperm output. Spermatozoa can then be retrieved by antegrade seminal tract washout (38). Spermatozoa retrieved by any of the aforementioned surgical techniques should always be cryopreserved for assisted reproductive procedures.
5.5 Conclusions and recommendation for obstructive azoospermia

Conclusions

Obstructive lesions of the seminal tract should be suspected in azoospermic or severely oligozoospermic patients with normal-sized testes and normal endocrine parameters.

Recommendation

In azoospermia caused by epididymal obstruction, standard procedures include vasovasostomy and tubulovasostomy.

Sperm retrieval techniques, such as MESA, TESE, and PESA, can be used additionally. These methods should be used only when cryostorage of the material obtained is available.

In azoospermia caused by epididymal obstruction, scrotal exploration with microsurgical epididymal sperm aspiration and cryopreservation of spermatozoa should be performed. Microsurgical reconstruction should be performed, if applicable. Results of reconstructive microsurgery depend on the cause and location of the obstruction, and the surgeon’s expertise.

6. VARICOCELE

6.1 Introduction
Varicocele is a common abnormality (see Chapter 2) with the following andrological implications:
• failure of ipsilateral testicular growth and development;
• symptoms of pain and discomfort;
• male infertility.

6.2 Classification
The following classification of varicocele (1,2) is useful in clinical practice:
• subclinical: not palpable or visible at rest or during Valsava manoeuvre, but can be shown by special tests (Doppler ultrasound studies) (3);
• grade 1: palpable during Valsava manoeuvre, but not otherwise;
• grade 2: palpable at rest, but not visible;
• grade 3: visible and palpable at rest.

6.3 Diagnosis
The diagnosis of varicocele is made by clinical examination and should be confirmed by colour Doppler analysis (2). In centres where treatment is carried out by antegrade or retrograde sclerotherapy or embolisation, diagnosis is additionally confirmed by X-ray.

6.4 Basic considerations
6.4.1 Varicocele and fertility
Varicocele is a physical abnormality present in 11.7% of adult men and in 25.4% of men with abnormal semen analysis (4). The exact association between reduced male fertility and varicocele is unknown, but a recent meta-analysis showed that semen improvement is usually observed after surgical correction (5). Current information fits with the hypothesis that in some men the presence of varicocele is associated with progressive testicular damage from adolescence onwards, and consequent reduction in fertility. Varicocele is associated with increased sperm DNA damage, and this sperm pathology may be secondary to varicocele-mediated oxidative stress. Varicocelectomy can reverse this sperm DNA damage, as shown in several studies (6).

6.4.2 Varicocelectomy
Varicocele repair has been a subject of debate for several decades: controversy exists as to whether varicocele repair results in more spontaneous pregnancies as compared to observation. The 2009 Cochrane Database review concluded that there is no evidence that treatment of varicocele improves a couples’ chance of conception (7). This meta-analysis was criticised for including several heterogeneous studies, men with normal semen analysis, and men with a subclinical varicocele (8). In three RCTs repair of a subclinical varicocele was found to be ineffective (9-11). Also, studies of men with a varicocele and normal semen analysis have shown no clear benefit of treatment over observation (12,13).

The duration of infertility also seems to be important. In a recent study it was shown that couples with infertility of > 2 years duration had a significantly higher pregnancy rate after varicocelectomy compared to couples with an uncorrected varicocele. In couples with a shorter duration of infertility, such a difference was not observed (14).

In a recent meta-analysis of four RCTs of varicocelectomy in men with a clinical varicocele,
oligospermia and otherwise unexplained infertility, there was a trend in favour of surgical correction (15). The combined OR was 2.23 (95% CI, 0.86-5.78; \( P = 0.091 \)), indicating that varicocelectomy was moderately superior to observation, but the effect was not statistically significant.

There is a need for a large, properly conducted RCT of varicocele treatment in men with abnormal semen from couples with otherwise unexplained subfertility (16). Although treatment of varicocele in infertile men may be effective, in adolescents there is a significant risk of overtreatment: most adolescents with a varicocele will have no problem achieving pregnancy later in life (17).

### 6.5 Treatment

Several treatments are available for varicocele (Table 9). The type of intervention chosen depends mainly on the experience of the therapist. Although laparoscopic varicocelectomy is feasible, it must be justified in terms of cost-effectiveness.

### 6.6 Conclusions and recommendations for varicocele

**Conclusions**

Current information supports the hypothesis that the presence of varicocele in some men is associated with progressive testicular damage from adolescence onwards and a consequent reduction in fertility.

Although the treatment of varicocele in adolescents may be effective, there is a significant risk of overtreatment.

Varicocele repair may be effective in men with subnormal semen analysis, a clinical varicocele and otherwise unexplained infertility.

**Recommendations**

Varicocele treatment is recommended for adolescents with progressive failure of testicular development documented by serial clinical examination.

No evidence indicates benefit from varicocele treatment in infertile men who have normal semen analysis or in men with subclinical varicocele. In this situation, varicocele treatment cannot be recommended (15-17).

Varicocele repair should be considered in case of a clinical varicocele, oligospermia, infertility duration of ≥ 2 years and otherwise unexplained infertility in the couple.

7. HYPOGONADISM

7.1 Introduction

Hypogonadism is characterised by impaired testicular function, which may affect spermatogenesis and/or testosterone synthesis. The symptoms of hypogonadism depend on the degree of androgen deficiency and if the condition develops before or after pubertal development of the secondary sex characteristics. The symptoms and signs of hypoandrogenism presenting before and after completion of puberty are provided in Table 10.

*Modified from Nieschlag et al. (1).
The aetiological and pathogenetic mechanisms of male hypogonadism can be divided into three main
categories:
1. Primary (hypergonadotrophic) hypogonadism due to testicular failure.
2. Secondary (hypogonadotrophic) hypogonadism caused by insufficient gonadotropin-releasing
   hormone (GnRH) and/or gonadotropin (FSH, LH) secretion.
3. Androgen insensitivity (end-organ resistance).
The most common conditions within these three categories are given in Table 11 (see also Chapter 4).

7.2 Hypogonadotrophic hypogonadism: aetiology, diagnosis and therapeutic management

Idiopathic hypogonadotrophic hypogonadism (IHH) is characterised by low levels of gonadotropins and sex
steroid in the absence of anatomical or functional abnormalities of the hypothalamic-pituitary-gonadal axis (2).
IHH may be an isolated condition or may be associated with anosmia/hyposmia (Kallmann syndrome). Genetic
factors causing a deficit of gonadotropins may act at the hypothalamic or pituitary level.
Mutations in candidate genes (X-linked or autosomal) can be found in ~30% of congenital cases (2) and
should be screened prior to assisted reproduction (3).
Acquired hypogonadotrophic hypogonadism can be caused by some drugs, hormones, anabolic
steroids, or tumours. A suspected tumour requires imaging [computed tomography (CT) or magnetic resonance imaging (MRI)] of the sella region and a complete endocrine work-up.
Failure of hormonal regulation can easily be determined (4). Endocrine deficiency leads to a lack of spermatogenesis and testosterone secretion as a result of decreased secretion of FSH and LH. After having excluded secondary forms (drugs, hormones, or tumours), the therapy of choice depends on whether the goal is to achieve normal androgen levels or fertility.
Normal androgen levels and subsequent development of secondary sex characteristics (in cases of
onset of hypogonadism before puberty) and a eugonadal state can be achieved by androgen replacement
alone. However, stimulation of sperm production requires treatment with human chorionic gonadotropin (hCG) combined with recombinant FSH or urinary FSH or human menopausal gonadotropins (HMGs). In the rare case of “fertile eunuchs”, who have sufficient production of FSH but not LH, treatment with hCG alone may be sufficient to stimulate sperm production and achieve normal testosterone levels (5).

If hypogonadotrophic hypogonadism is hypothalamic in origin, an alternative to hCG treatment is pulsatile GnRH (6). In patients who have developed hypogonadism before puberty and have not been treated with gonadotropins or GnRH, 1-2 years of therapy may be needed to achieve sperm production. Once pregnancy has been established, patients can return to testosterone substitution.

### 7.3 Hypergonadotrophic hypogonadism: aetiology, diagnosis and therapeutic management

Many conditions in men are associated with hypergonadotrophic hypogonadism (Table 11, see also Chapter 4). Most conditions listed in Table 11 only affect the reproductive function of the testes so that only FSH level is elevated. However, it has been reported that men with infertility are at higher risk for developing impaired Leydig cell function (7), while men with Klinefelter’s syndrome often show high LH values and develop hypoandrogenism with ageing (8). A decrease in testosterone blood concentrations after extensive testicular biopsy in the context of TESE/ICSI has been observed, raising questions about the need for long-term endocrine follow-up of these patients (9).

Hypogonadism affecting both reproductive and endocrine functions of the testes occurs after treatment with GnRH analogues or surgical castration for prostatic cancer (10).

Laboratory diagnosis of hypergonadotrophic hypogonadism is based on a high level of FSH, decreased serum testosterone, and increased LH levels (3). Testosterone levels should be evaluated in view of the serum concentration of sex hormone binding globulin (SHBG). Based on levels of total testosterone, albumin and SHBG, free and bioavailable testosterone can be calculated (http://www.issam.ch/freetesto.htm).

Due to diurnal variation, blood samples for testosterone assessment should be taken before 10.00 h. The existing guidelines for androgen replacement are based on presence of symptoms of hypogonadism and total testosterone levels. There is general agreement that a total testosterone level > 12 nmol/L (350 ng/dL) does not require substitution. Similarly, based on the data of younger men, there is consensus that patients with serum total testosterone levels < 8 nmol/L (230 ng/dL) will usually benefit from testosterone treatment. For the group with serum total testosterone level between 8 and 12 nmol/L (in repeated samples), a 3-6-month trial period with testosterone supplementation can be considered. Generally, androgen replacement should not be given to men not presenting with symptoms of hypogonadism.

Testosterone suppresses pituitary production of LH and FSH, therefore, replacement therapy should not be given for infertility.

In obese men, decision-making may be helped by measuring total testosterone with SHBG to calculate free testosterone or measurement of free testosterone by equilibrium dialysis (11). Injectable, oral and transdermal testosterone preparations are available for clinical use (3). The best preparation to use is one that maintains serum testosterone levels within the physiological concentration (11-13). See also EAU Guidelines on Hypogonadism (14).

8. CRYPTORCHIDISM

8.1 Introduction
Cryptorchidism is the most common congenital abnormality of the male genitalia and is found in 2-5% of newborn boys, depending on gestational age (cryptorchidism occurs more often in premature boys) and age after birth. At the age of 3 months, the incidence of cryptorchidism falls spontaneously to 1-2%. Approximately 20% of undescended testes are non-palpable and may be located within the abdominal cavity.

The aetiology of cryptorchidism is multifactorial, involving disrupted endocrine regulation and several gene defects. The normal descent of the testes requires a normal hypothalamic-pituitary-gonadal axis. Endocrine disruption in early pregnancy can potentially affect gonadal development and normal descent of the testes; however, most boys with maldescended testes show no endocrine abnormalities after birth. It has been postulated that cryptorchidism may be a part of the so-called testicular dysgenesis syndrome (TDS), which is a developmental disorder of the gonads caused by environmental and/or genetic influences early in pregnancy. Besides cryptorchidism, TDS includes hypospadias, reduced fertility, increased risk of malignancy, and Leydig cell dysfunction (1).

8.2 Incidence of cryptorchidism
The Caucasian population has a threefold higher incidence of cryptorchidism compared to African-Americans. Even between Caucasians, there are significant differences in the risk of cryptorchidism, for example, it is significantly more common among Danish than Finnish newborns (2). Premature babies have a much higher
incidence of cryptorchidism than full-term babies. In a British study, the incidence of cryptorchidism was 2.7% in > 3,000 boys weighing > 2.5 kg and 21% in premature boys weighing < 2.5 kg. At the age of 3 months, spontaneous descent occurred in most boys, and the incidence of cryptorchidism fell to 0.9% and 1.7%, in the > 2.5 kg and < 2.5 kg group, respectively (3).

8.3  Testicular descent and maldescent
The process of testicular descent has two distinct phases: transabdominal and inguinal. During transabdominal descent, development of the gubernaculum and genitoinguinal ligament plays an important role. The anti-Mullerian hormone regulates transabdominal descent of the testes. Induction of the gubernaculum depends on a functional Insl3 gene in mice (4). This gene is expressed in Leydig cells and its targeted deletion causes bilateral cryptorchidism with free-moving testes and genital ducts (5). Androgens play an important role in both phases of testicular descent, whereas other gene families, for example, the homeobox (HOX) and GREAT/RXFP2 genes (G-protein-coupled receptor affecting testis descent), are important in the development of genital organs and may be associated with testicular maldescent (6,7).

8.4  Hormonal control of testicular descent
Maldescent can be caused by two hormonal factors: hypogonadism and androgen insensitivity. The increasing incidence of reproductive abnormalities in male humans can be explained by increased oestrogen exposure during gestation (8). Some pesticides and synthetic chemicals act as hormonal modulators, often possessing oestrogenic activity (xeno-oestrogens) (9). The oestrogenic and antiandrogenic properties of these chemicals may cause hypospadias, cryptorchidism, reduced sperm density, and an increased incidence of testicular tumours in animal models, via receptor-mediated mechanisms or direct toxic effects associated with Leydig cell dysfunction (10).

8.5  Pathophysiological effects in maldescended testes

8.5.1  Degeneration of germ cells
The degeneration of germ cells in maldescended testes is apparent after the first year of life. Degenerative changes vary, depending on the position of the testis (11). During the second year, the number of germ cells declines. In 10-45% of affected patients, the complete loss of germ cells can be detected. Early treatment is therefore recommended to conserve spermatogenesis; especially in bilateral cases. Surgical treatment is the most effective and reliable method of bringing testes into the scrotum. Hormone treatment with hCG has been used widely in the past, but it has now been abolished because of increased germ cell apoptosis after treatment (12).

8.5.2  Relationship with fertility
Semen parameters are often impaired in men with a history of cryptorchidism (13). Surgical treatment during the first or second year of life may have a positive effect on subsequent fertility (14). However, there is no definitive proof of the protective effect of early orchidopexy. In men with a history of unilateral cryptorchidism, paternity is almost equal (89.7%) to that in men without cryptorchidism (93.7%).

In men with unilateral cryptorchidism, paternity is independent of age at orchidopexy and preoperative testicular location and size (15). However, a history of unilateral cryptorchidism may result in reduced fertility potential and therefore a longer time to achieve pregnancy.

In men with bilateral cryptorchidism, oligozoospermia can be found in 31% and azoospermia in 42%. In cases of bilateral cryptorchidism, the rate of paternity is only 35-53%. In cases of bilateral cryptorchidism and azoospermia, orchidopexy performed even in adult life might lead to the appearance of spermatozoa in the ejaculate (16).

8.5.3  Germ cell tumours
Cryptorchidism is a risk factor for testicular cancer and is associated with testicular microcalcification and intratubular germ cell neoplasia of unclassified type (ITGCNU); formerly CIS of the testes. In 5-10% of testicular cancers, there is a history of cryptorchidism (17). The risk of a germ cell tumour (GCT) is 3.6-7.4 times higher than in the general population and 2-6% of men with a history of cryptorchidism will develop a testicular tumour (17). Orchidopexy performed before the age of puberty has been reported to decrease the risk of testicular cancer (18). However, this and other similar reports are based on retrospective data and do not exclude the possibility that boys undergoing early and late orchidopexy represent different pathogenetic groups of testicular maldescent.

8.6  Treatment of undescended testes

8.6.1  Hormonal treatment
Human chorionic gonadotropin or GnRH has been used widely in the past to treat cryptorchidism. Although
15-20% of retained testes descend during hormonal treatment, one-fifth of these reascend later. Also, treatment with hCG may be harmful to future spermatogenesis by increasing the apoptosis of germ cells (12), which is why hormonal treatment is no longer recommended.

8.6.2 Surgical treatment

The success rate of surgical treatment for undescended testes is 70-90% (19). If the spermatic cords or the spermatic vessels are too short to allow proper mobilisation of the testis into the scrotum, a staged orchidopexy (Fowler-Stephenson procedure) can be performed, using open surgery, laparoscopy, or microsurgery.

The optimal age for performing orchidopexy is still debated. Some retrospective studies have indicated that early treatment (during the first 2 years of life) has a beneficial effect on preserving future fertility (20), whereas a recent randomised study showed that surgery at 9 months resulted in a partial catch-up of testicular growth until at least age 4 years versus surgery at 3 years (21). The results clearly indicate that early surgery has a beneficial effect on testicular growth. Testicular volume is an approximate indirect measure of spermatogenic activity, therefore, it is possible that orchidopexy at an early age might improve future spermatogenesis.

A biopsy at the time of orchidopexy (see Section 8.5.3) can reveal (ITGCNU), which can be removed, thereby preventing development of a malignant tumour. If not corrected by adulthood, an undescended testis should not be removed because it still produces testosterone. Furthermore, as indicated above, correction of bilateral cryptorchidism, even in adulthood, can lead to sperm production in previously azoospermic men (16).

Vascular damage is the most severe complication of orchidopexy and can cause testicular atrophy in 1-2% of cases. In men with non-palpable testes, the postoperative atrophy rate was 12% in those cases with long vascular pedicles that enabled scrotal positioning. Postoperative atrophy in staged orchidopexy has been reported in up to 40% of patients (19).

9. IDIOPATHIC MALE INFERTILITY

9.1 Introduction
No demonstrable cause of infertility is found in at least 44% of infertile men (1).

9.2 Empirical treatments
A wide variety of empirical drug treatments of idiopathic male infertility have been used; however, there is little scientific evidence for an empirical approach (2). Androgens, hCG/HMG, bromocriptine, alpha-blockers, systemic corticosteroids and magnesium supplementation are not effective in the treatment of OAT syndrome. Follicle-stimulating hormone (3) might be beneficial in a selection of patients (3). A Cochrane analysis showed that men taking oral antioxidants had an associated significant increase in live birth rate (pooled OR = 4.85; 95% CI: 1.92-12.24; P = 0.0008; I(2) = 0%) when compared with men taking the control treatment. No studies have reported harmful side effects from antioxidant therapy. The evidence suggests that antioxidant supplementation in subfertile men may improve the outcomes of live birth and pregnancy rate for subfertile couples undergoing assisted reproduction technique (ART) cycles. Further head-to-head comparisons are necessary to identify the superiority of one antioxidant over another (4).

Recommendation GR
Medical treatment of male infertility is recommended only for cases of hypogonadotrophic hypogonadism.

9.3 References

10. MALE CONTRACEPTION

10.1 Introduction
“Male contribution to contraception” is a more accurate phrase than “male contraception”, because men do not conceive. Development of male contraceptive methods is important because up to 40% of women have an unmet need for family planning, with approximately 80 million women every year having unintended or unwanted pregnancies (1).

Three of the four methods of male contraception have been in use for hundreds of years (i.e., condoms, periodic abstinence, and withdrawal). The typical first-year failure rates of traditional male methods are high (withdrawal 19%, periodic abstinence 20%, and condoms 3-14%) compared to the failure rates of 0.1-3% for modern reversible female methods (2). For men to take more responsibility for family planning, male contraceptive methods must be acceptable, cheap, reversible, and effective.

Research is attempting to (3):
• Prevent sperm production by using exogenic androgens, progestogen, and GnRH formulations in various combinations.
• Interfere with the ability of sperm to mature and fertilise, by using an epididymal approach to create a hostile environment for sperm.
• Produce better barrier methods (e.g., polyurethane condoms can be used by those with latex allergy, although they have higher breakage rates) (4).
• Produce an antisperm contraceptive vaccine (5).
• Inhibit sperm-egg interactions.

These approaches remain experimental. The method nearest to being generally available clinically is hormonal male contraception, which is based on the suppression of gonadotropins and testosterone substitution to maintain male sexual function and bone mineralization, and to prevent muscle wasting (6). Various contraceptive regimens have been developed and tested, including testosterone monotherapy, androgen/ progestin combinations, testosterone with GnRH analogues, and selective androgen- and progestin-receptor modulators. There are racial differences in the response to androgens alone. However, a combination of testosterone with progesterin results in complete suppression of spermatogenesis in all races, and provides contraceptive efficacy equivalent to female hormonal methods (7). Phase III clinical trials of depot preparations of androgen/progestin combinations are in progress.

10.2 Vasectomy
Vasectomy is an effective method of permanent male surgical sterilisation (8). Extensive guidelines on vasectomy were published by the EAU in 2012 (9). Before vasectomy, the couple should be fully informed about the benefits and risks, especially as an Australian telephone survey found that 9.2% of respondents regretted having a vasectomy (10).

10.2.1 Surgical techniques
Various techniques are available for vasectomy. The least invasive approach is no-scalpel vasectomy (11), which is also associated with a low rate of complications (12). The most effective occlusion technique is cauterisation of the lumen of the vas deferens and fascial interposition (13-15). Most techniques can be carried out safely under local anaesthesia in an outpatient clinic.

10.2.2 Complications
Vasectomy does not significantly alter spermatogenesis and Leydig cell function. The volume of ejaculate remains unchanged. Potential systemic effects of vasectomy, including atherosclerosis, have not been proven, and there is no evidence of a significant increase in any systemic disease after vasectomy. An increased rate of prostate cancer in men who underwent vasectomy has not been detected (16,17). Acute local complications associated with vasectomy include haematoma, wound infection, and epididymitis in up to 5% of cases (17). The potential long-term complications (e.g., chronic testicular pain) (18) must be discussed with the patient before the procedure. Epididymal tubal damage is common, and is associated with consequent development of sperm granuloma and time-dependent secondary epididymal obstruction, which limits vasectomy reversal.

10.2.3 Vasectomy failure
If an effective occlusion technique is used, the risk of recanalisation after vasectomy should be < 1% (12). However, patients should be informed preoperatively that, although rare, long-term recanalisation might occur (19). No motile spermatozoa should be detected 3 months after vasectomy. Persistent motility is a sign of vasectomy failure, and the procedure will need to be repeated. A “special clearance” with non-motile spermatozoa < 10,000/mL is still under discussion (20).

10.2.4 Counselling
Counselling with regard to vasectomy must address the following aspects:
• Vasectomy should be considered irreversible.
• Vasectomy is associated with a low complication rate; however, because it is an elective operation, even small risks must be explained, because men (and their partners) might wish to consider these before giving consent.
• Vasectomy can fail, although the failure rate is low.
• Couples should be advised to continue with other effective contraception until clearance is confirmed.
• All available data indicate that vasectomy is not associated with any serious, long-term, side effects (15).
• Vasectomy involving cauterisation and fascial interposition appears to be the most effective technique (12-14).
10.3 Vasectomy reversal
A wide range of surgical success rates has been published for vasectomy reversal (up to 90%), depending on the time between vasectomy and re-fertilisation, type of vasectomy (e.g., open-ended or sealed), type of reversal (vasovasostomy or vasoepididymostomy), and whether reversal was unilateral or bilateral. However, there have been no RCTs comparing macrosurgery (loops) and microsurgery. Microsurgical techniques with the help of magnification and smaller suture materials should be used (21).

10.3.1 Length of time since vasectomy
Vasovasostomy results have shown patency rates up to 90%. The longer the interval is from vasectomy to reversal, the lower is the pregnancy rate. In a study of 1,469 men who had undergone microsurgical vasectomy reversal, patency and pregnancy rates were 97% and 76%, respectively, for an interval up to 3 years after vasectomy; 88% and 53% for 3-8 years, 79% and 44% for 9-14 years, and 71% and 30% for > 15 years (22).

10.3.2 Tubulovasostomy
The chance of secondary epididymal obstruction after vasectomy increases with time. After an interval of 10 years, 25% of men appear to have epididymal blockage. If secondary epididymal obstruction occurs, tubulovasostomy is needed to reverse the vasectomy (see Chapter 5) (23).

10.3.3 Microsurgical vasectomy reversal versus epididymal or testicular sperm retrieval and ICSI
According to the calculations of cost per delivery for vasectomy reversal versus sperm retrieval/ICSI, under a wide variety of initial assumptions, it is clear that vasectomy reversal is associated with a considerably lower cost per delivery and higher delivery rates (24,-27). Sperm retrieval and ICSI must yield an 81% pregnancy rate per cycle to achieve equal costs to vasectomy reversal.

11. MALE ACCESSORY GLAND INFECTIONS AND INFERTILITY

11.1 Introduction
Infections of the male urogenital tract are potentially curable causes of male infertility (1-3). The WHO considers urethritis, prostatitis, orchitis and epididymitis to be male accessory gland infections (MAGIs) (2). However, specific data are not available to confirm that these diseases have a negative influence on sperm quality and male fertility in general.

In order to keep the guidelines as short as possible, the MAGI section is discussed in detail in the Guidelines for Urological Infections and Chronic Pelvic Pain (4,5).

11.2. Ejaculate analysis
11.2.1 Introduction
Ejaculate analysis (see Chapter 2) clarifies whether the prostate is involved as part of a generalised MAGI and provides information about sperm quality. In addition, leukocyte analysis allows differentiation between inflammatory and non-inflammatory chronic pelvic pain syndrome (CPPS) (NIH IIa vs NIH IIIb).

11.2.2 Microbiological findings
After exclusion of urethritis and bladder infection, > 10⁶ peroxidase-positive white blood cells (WBCs) per millilitre of ejaculate indicate an inflammatory process. In this case, a culture should be performed for common urinary tract pathogens, particularly Gram-negative bacteria.

A concentration of > 10³ cfu/mL urinary tract pathogens in the ejaculate is indicative of significant bacteriospermia. Various microorganisms are found in the genital tract of men seen in infertility clinics; usually with more than one strain of bacteria present (1). The sampling time can influence the positive rate of microorganisms in semen and the frequency of isolation of different strains (6). The ideal diagnostic test for Chlamydia trachomatis in semen has not yet been established (7). In contrast to serological findings in women, antibody tests for C. trachomatis in seminal plasma are not indicative if no type-specific methods are used (7).

Ureaplasma urealyticum is pathogenic only in high concentrations (> 10³ cfu/mL ejaculate). No more than about 10% of samples analysed for ureaplasma exceed this concentration (8). Normal colonisation of the urethra hampers the clarification of mycoplasma-associated urogenital infections, using samples such as the ejaculate (9).

11.2.3 White blood cells
The clinical significance of an increased concentration of leukocytes in the ejaculate is controversial (10). Infection is indicated only by an increased level of leukocytes (particularly polymorphonuclear leukocytes) and their products (e.g., leukocyte elastase) secreted into the seminal fluid. Most leukocytes are neutrophilic granulocytes, as suggested by the specific staining of the peroxidase reaction (2). Although leukocytospermia is a sign of inflammation, it is not necessarily associated with bacterial or viral infections (11). Earlier findings have shown that elevated leukocyte numbers are not a natural cause of male infertility (12). According to WHO classification, leukocytospermia is defined as > 10⁶ WBCs/mL. Only two studies have analysed alterations of WBCs in the ejaculate of patients with proven prostatitis (13,14). Both studies found more leukocytes in men with prostatitis compared to those without inflammation (CPPS, type NIH IIIb).

11.2.4 Sperm quality
The deleterious effects of chronic prostatitis on sperm density, motility and morphology are under debate (1). All investigations have given contradictory results, and have not confirmed that chronic prostatitis has a decisive role in altering conventional semen parameters (15-17).

11.2.5 Seminal plasma alterations
Seminal plasma elastase is a biochemical indicator of polymorphonuclear lymphocyte activity in the ejaculate (1,18,19), with a suggested cut-off level of approximately 600 ng/mL (1). Various cytokines are involved in
inflammation and can influence sperm function. Several studies have investigated the association between interleukin (IL) concentration, leukocytes, and sperm function (20-22), but no correlations have been found. The prostate is the main site of origin of IL-6 and IL-8 in the seminal plasma. Cytokines, especially IL-6, play an important role in the male accessory gland inflammatory process (23). However, elevated cytokine levels do not depend on the number of leukocytes in expressed prostatic secretion (EPS) (24).

11.2.6 **Glandular secretory dysfunction**
Infections of the sex glands can impair their excretory function. Decreased quantities of citric acid, phosphatase, fructose, zinc, and α-glutamyl-transferase activity are indicators of disturbed prostatic secretory parameters (1). Reduced fructose concentration indicates impaired vesicular function (8,25).

11.2.7 **Sperm antibodies**
Serum antibodies to sperm antigens are not useful in the diagnosis of immune infertility. Early studies found an association between increased levels of sperm antibodies in serum and non- or abacterial prostatitis (26,27). However, except for suspected chlamydial infections (28), only a history of vasectomy is predictive of sperm antibody formation (29).

11.2.8 **Reactive oxygen species**
Reactive oxygen species might be increased in chronic urogenital infections associated with increased leukocyte numbers (30). However, their biological significance in prostatitis remains unclear (1).

11.2.9 **Therapy**
Treatment of chronic prostatitis is usually targeted at relieving symptoms (31,32). Andrologically, the aims of therapy for altered semen composition in male adnexitis (acute and chronic infections of the male urogenital tract) are:

- reduction or eradication of microorganisms in prostatic secretions and semen;
- normalisation of inflammatory (e.g., leukocytes) and secretory parameters;
- improvement of sperm parameters to counteract fertility impairment (33).

Treatment includes antibiotics, anti-inflammatory drugs, surgical procedures, normalisation of urine flow, physical therapy, and alterations in general and sexual behaviour.

Only antibiotic therapy of chronic bacterial prostatitis (NIH II) has provided symptomatic relief, eradication of microorganisms, and a decrease in cellular and humoral inflammatory parameters in urogenital secretions. The use of α-blockers for symptom relief is controversial. Although antibiotics might improve sperm quality (33), there is no evidence that treatment of chronic prostatitis increases the probability of conception (1,34).

**11.3 Epididymitis**

11.3.1 **Introduction**
Inflammation of the epididymis causes unilateral pain and swelling, usually with acute onset. Among sexually active men < 35 years of age, epididymitis is most often caused by *C. trachomatis* or *Neisseria gonorrhoea* (35,36). Sexually transmitted epididymitis is usually accompanied by urethritis. Non-sexually transmitted epididymitis is associated with urinary tract infection and occurs more often in men aged > 35 years, those who have recently undergone urinary tract instrumentation or surgery, and those who have anatomical abnormalities (37).

11.3.2 **Ejaculate analysis**
Ejaculate analysis according to WHO criteria, including leukocyte analysis, might indicate persistent inflammatory activity. In many cases, transiently decreased sperm counts and forward motility are observed (36,38,39). Ipsilateral low-grade orchitis (40,41) might be the cause of this slight impairment in sperm quality (Table 14) (42).

Development of stenosis in the epididymal duct, reduction of sperm count, and azoospermia are more important in the follow-up of bilateral epididymitis (see Chapter 5). The extent of azoospermia after epididymitis is unclear.

11.3.3 Treatment

Antibiotic therapy is indicated before culture results are available (Table 13). Treatment of epididymitis results in:
- microbiological cure of infection;
- improvement of clinical signs and symptoms;
- prevention of potential testicular damage;
- prevention of transmission;
- decrease of potential complications (e.g., infertility or chronic pain).

Patients with epididymitis known or suspected to be caused by *N. gonorrhoeae* or *C. trachomatis* must be told to refer their sexual partners for evaluation and treatment (47).

11.4 Conclusions and recommendations for male accessory gland infections

**Conclusions**

- Urethritis and prostatitis are not associated clearly with male infertility. 3
- Antibiotic treatment often only eradicates microorganisms; it has no positive effect on inflammatory alterations, and cannot reverse functional deficits and anatomical dysfunction. 2a
- Although antibiotic treatment for MAGI might provide improvement in sperm quality, it does not necessarily enhance the probability of conception. 2a

**Recommendations**

- Patients with epididymitis that is known or suspected to be caused by *N. gonorrhoeae* or *C. trachomatis* must be instructed to refer their sexual partners for evaluation and treatment. B

12. GERM CELL MALIGNANCY AND TESTICULAR MICROCALCIFICATION

12.1 Germ cell malignancy and male infertility
Testicular germ cell tumour (TGCT) is the most common malignancy in Caucasian men aged 15-40 years and affects approximately 1% of subfertile men. The lifetime risk of TGCT varies between ethnic groups and countries. The highest annual incidence of TGCT occurs in Caucasians, and varies from 10/100,000 (e.g., in Denmark and Norway) to 2/100,000 (e.g., in Finland and the Baltic countries). Generally, seminomas and non-seminomas are preceded by CIS, and untreated ITGCNU will eventually progress to invasive cancer (1,2).

The most convincing evidence for a general decline in male reproductive health is the increase in testicular cancer seen in western countries (3). In almost all countries with reliable cancer registers, the incidence of testicular cancer has increased (4). Cryptorchidism and hypospadias are associated with an increased risk of testicular cancer; men with cryptorchidism and/or hypospadias are over-represented among patients with testicular cancer.

Men with dysgenic testes have an increased risk of developing testicular cancer in adulthood. These cancers arise from premalignant gonocytes or CIS cells (5). Testicular microlithiasis (TM), seen on ultrasound, can be associated with GCT and CIS of the testes.

12.2 Testicular germ cell cancer and reproductive function
Men with TGCT have decreased semen quality, even before cancer is diagnosed (6). Orchidectomy implies a risk of azoospermia in these men, with sperm found in the ejaculate before the tumour-bearing testis has been removed. Semen cryopreservation before orchidectomy should therefore be considered (see Chapter 14). Treatment of TGCT can result in additional impairment of semen quality (7).

In addition to spermatogenic failure, patients with TGCT have Leydig cell dysfunction, even in the contralateral testis (8). The risk of hypogonadism may therefore be increased in men treated for TGCT. The measurement of pretreatment levels of testosterone, SHBG, LH and oestradiol might help to anticipate post-treatment hypogonadism. Men who have had TGCT and have low normal androgen levels should receive long-term follow-up because they are at risk of developing hypogonadism as a result of an age-related decrease in testosterone production (9).

The risk of hypogonadism is most pronounced in TGCT patients treated with > 3 cycles of chemotherapy or irradiation of retroperitoneal lymph nodes. However, this risk is greatest at 6-12 months post-treatment. This suggests there may be some improvement in Leydig cell function, and why it is reasonable to expect initiation of androgen replacement, until the patient shows continuous signs of testosterone deficiency, even at 2 years follow-up (10). The risk of low libido and erectile dysfunction is also increased in TGCT patients (11).

12.3 Testicular microlithiasis
Microcalcification inside the testicular parenchyma can be found in 0.6-9% of men referred for testicular ultrasound (12-14). Although the true incidence of microcalcification in the general population is unknown, it is probably rare. However, ultrasound findings of TM are common in men with TGCT, cryptorchidism, testicular dysgenesis, infertility, testicular torsion and atrophy, Klinefelter’s syndrome, hypogonadism, male pseudohermaphroditism, varicocele, epididymal cysts, pulmonary microlithiasis, and non-Hodgkin’s lymphoma. The incidence reported seems to be higher with high-frequency ultrasound machines (16).

The relationship between TM and infertility is unclear, but probably relates to dysgenesis of the testes, with degenerate cells being sloughed inside an obstructed seminiferous tubule and failure of the Sertoli cells to phagocytose the debris. Subsequently, calcification occurs.

Testicular microlithiasis is found in testes at risk of malignant development. The reported incidence of TM in men with TGCT is 6-46% (17-19), and TM should therefore be considered premalignant. Testicular
biopsies from men with TM have found a higher prevalence of CIS, especially in those with bilateral microlithiasis (20). However, TM is found most often in men with a benign testicular condition and the microcalcification itself is not malignant.

Further investigation of the association between TM and CIS will require testicular biopsies in large series of men without signs of TGCT. However, available data indicate that men in whom TM is found by ultrasound, and who have an increased risk of TGCT, should be offered testicular biopsy for detection of CIS. The list of high-risk patients includes men with infertility and bilateral TM, atrophic testes, undescended testes, a history of TGCT, and contralateral TM (21).

13. DISORDERS OF EJACULATION

13.1 Definition
Disorders of ejaculation are uncommon, but important, causes of male infertility. This group includes several heterogeneous dysfunctions, which can be either organic or functional.

13.2 Classification and aetiology
13.2.1 Anejaculation
Anejaculation involves complete absence of antegrade or retrograde ejaculation. It is caused by failure of semen emission from the seminal vesicles, prostate and ejaculatory ducts into the urethra (1). True anejaculation is usually associated with a normal orgasmic sensation. Occasionally (e.g., in incomplete spinal cord injuries), this sensation is altered or decreased. True anejaculation is always associated with central or peripheral nervous system dysfunction or with drugs (2) (Table 15).

13.2.2 Anorgasemia
Anorgasemia is the inability to reach orgasm and can give rise to anejaculation. Anorgasemia is often a primary condition and its cause is usually psychological. Some patients report sporadic events of nocturnal emission or of ejaculation during great emotional excitement unrelated to sexual activity (3).

13.2.3 Delayed ejaculation
In delayed ejaculation, abnormal stimulation of the erect penis is needed to achieve orgasm with ejaculation.
Delayed ejaculation can be considered a mild form of anorgasmia, and both conditions can be found alternately in the same patient. The causes of delayed ejaculation can be psychological, organic (e.g., incomplete spinal cord lesion (3) or iatrogenic penile nerve damage (4), or pharmacological [e.g., selective serotonin re-uptake inhibitors (SSRIs), antihypertensives, or antipsychotics] (5).

### Retrograde ejaculation

Retrograde ejaculation is the total, or sometimes partial, absence of antegrade ejaculation as a result of semen passing backwards through the bladder neck into the bladder. Patients experience a normal or decreased orgasmic sensation, except in paraplegia. Partial antegrade ejaculation must not be confused with the secretion of bulbourethral glands. The causes of retrograde ejaculation can be divided into neurogenic, pharmacological, or urethral, or bladder neck incompetence (Table 15).

### Asthenic ejaculation

Asthenic ejaculation, also defined as partial ejaculatory incompetence or “ejaculation baveuse” (5), is characterised by an altered propulsive phase, with a normal emission phase. The orgasmic sensation is reduced and the typically rhythmical contractions associated with ejaculation are missing, whereas in asthenic ejaculation caused by urethral obstruction, these contractions are present. Asthenic ejaculation generally is caused by the neurogenic or urethral pathologies already listed in Table 16. Asthenic ejaculation does not usually affect semen quality.

### Premature ejaculation

The International Society for Sexual Medicine (ISSM) has adopted the first evidence-based definition of lifelong premature ejaculation (PE): “Premature ejaculation is a male sexual dysfunction characterised by ejaculation which always or nearly always occurs prior to or within about one minute of vaginal penetration; and inability to delay ejaculation on all or nearly all vaginal penetrations; and negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy”.

Premature ejaculation may be strictly organic (e.g., prostatitis-related) or psychogenic, partner-related or non-selective, and can be associated with erectile dysfunction. It does not impair fertility, provided intravaginal ejaculation occurs.

### Painful ejaculation

Painful ejaculation is usually an acquired condition that is often related to lower urinary tract symptoms (6). It sometimes causes moderate sexual dysfunction. The painful sensation might be felt in the perineum, or urethra and urethral meatus (7). It can be caused by ejaculatory duct obstruction, all types of chronic prostatitis/CPPS, urethritis, urethrocele, antidepressant drugs, and psychological problems.

### Diagnosis

Diagnostic management includes the following recommended procedures.

#### Clinical history

The patient must be carefully checked for diabetes, neuropathy, trauma, urogenital infection, previous surgery,
and medication. Particular attention must be paid to the characteristics of micturition and ejaculation (presence of nocturnal emission, ejaculatory ability in given circumstances, and primary or acquired disorder), as well as to psychosexual aspects (education, features of affective relationship, pre-existent psychological trauma, and previous psychological therapy).

13.3.2 Physical examination
Genital and rectal examinations are conducted, including evaluation of the prostate, bulbocavernosus reflex, and anal sphincter tone. Minimal neurological tests include:
- sensitivity of scrotum, testes, and perineum;
- cremasteric and abdominal cutaneous reflex;
- leg osteotendinous and plantar reflexes.

13.3.3 Post-ejaculatory urinalysis
Post-ejaculatory urinalysis of centrifuged urine can be used to determine if there is total or partial retrograde ejaculation.

13.3.4 Microbiological examination
Initial, mid-stream urine, EPS, and/or urine after prostatic massage are cultured for evidence of prostatic infection. In cases of increased leukocytes in semen, semen culture or biochemical infection marker tests are also suggested (8).

13.3.5 Optional diagnostic work-up
This diagnostic work-up can include:
- neurophysiological tests (bulbocavernosus evoked response and dorsal nerve somatosensory evoked potentials);
- tests for autonomic neuropathy;
- psychosexual evaluation;
- videocystometry;
- cystoscopy;
- transrectal ultrasonography;
- uroflowmetry;
- vibratory stimulation of the penis.

13.4 Treatment
Infertility caused by disorders of ejaculation is seldom treated on the basis of aetiology. Treatment usually involves retrieval of spermatozoa for use in ARTs. The following aspects must be considered when selecting treatment:
- age of patient and his partner;
- psychological problems of the patient and his partner;
- couple’s willingness and acceptance of different fertility procedures;
- associated pathology;
- psychosexual counselling.

13.5 Aetiological treatment
If possible, any pharmacological treatment that is interfering with ejaculation should be stopped. In painful ejaculation, tamsulosin can be administered during antidepressant treatment (9). Treatment should be given for urogenital infections (i.e., in cases of painful ejaculation) (8). Dapoxetine is an SSRI that has been introduced for the therapy of PE (10), because it appears that PE is related to serotonin levels. If possible, any underlying urethral pathology or metabolic disorder (e.g., diabetes) should be corrected. Psychotherapy is usually not very effective.

13.6 Symptomatic treatment
13.6.1 Premature ejaculation
Premature ejaculation can be treated with the SSRI dapoxetine, topical anaesthetic agents to increase intravaginal ejaculation latency time, behavioural therapy, and/or psychotherapy. Off-label use of SSRIs (e.g., paroxetine and fluoxetine) should be applied with caution.

13.6.2 Retrograde ejaculation
In the absence of spinal cord injury, anatomical anomalies of the urethra, or pharmacological agents, drug treatment must be used to induce antegrade ejaculation (Table 16). Alternatively, the patient can be
encouraged to ejaculate when his bladder is full to increase bladder neck closure (11).

</table>

Sperm collection from post-orgasmic urine for use in ART is recommended if:
- drug treatment is ineffective or intolerable as a result of side effects;
- the patient has a spinal cord injury;
- drug therapy inducing retrograde ejaculation cannot be interrupted.

Sperm retrieval is timed to coincide with the partner’s ovulation. Urine must be alkalised (pH 7.2-7.8) and osmolality must be 200-300 mOsmol/kg. Alternatively, a catheter can be inserted into the bladder to allow instillation of 10-50 mL Tyrode’s or Ham’s F-10 medium. The patient must ejaculate, and a second catheterisation is carried out immediately to retrieve spermatozoa. The latter treatment minimises contact between spermatozoa and urine (17,18).

If the biological sperm preparation is not of sufficient quality for intrauterine insemination, the couple must undergo in vitro reproductive procedures (e.g., ICSI) with fresh or cryopreserved spermatozoa. In the case of insufficient drug therapy, testicular (TESE or PESA) or epididymal (MESA) sperm retrieval techniques can be used for assisted reproduction.

**13.6.3 Anejaculation**

Drug treatment for anejaculation caused by lymphadenectomy and neuropathy, or psychosexual therapy for anorgasmia is not very effective. In all these cases, and in men who have a spinal cord injury, vibrostimulation (i.e., application of a vibrator to the penis) is first-line therapy.

In anejaculation, vibrostimulation evokes the ejaculation reflex (19), which requires an intact lumbosacral spinal cord segment. Complete spinal injuries and injuries above T10 show a better response to vibrostimulation. Once the safety and efficacy of this procedure has been assessed, patients can manage the process in their own home. Intravaginal insemination using a 10-mL syringe during ovulation can be carried out. If the quality of semen is poor, or ejaculation is retrograde, the couple may enter an IVF programme.

If vibrostimulation has failed, electroejaculation is the therapy of choice (20). Electroejaculation involves electrical stimulation of the periprostatic nerves via a probe inserted into the rectum, which seems unaffected by reflex arc integrity. Anaesthesia is required except in cases of complete spinal cord injury. In 90% of patients, electrostimulation induces ejaculation, which is retrograde in one-third of cases. Semen quality is often poor and most couples will need to enter an IVF programme (21).

When electroejaculation fails or cannot be carried out, sperm can be retrieved from the seminal ducts by aspiration from the vas deferens (22) (see Chapter 5) or seminal tract washout (23).

When sperm cannot be retrieved, epididymal obstruction or testicular failure must be suspected. If only immotile sperm can be retrieved, DNA damage is very likely and will yield poor IVF results. TESE can then be used (8,24). Anejaculation following either surgery for testicular cancer or total mesorectal excision can be prevented using monolateral lymphadenectomy or autonomic nerve preservation (24), respectively.

14. SEMEN CRYOPRESERVATION

14.1 Definition
Cryopreservation is the storage of biological material at subzero temperatures [e.g., -80 or -196°C (the boiling point of liquid nitrogen)], at which biochemical processes of cell metabolism are slowed or interrupted. At -196°C, the biochemical reactions that lead to cell death are stopped.

14.2 Introduction
Cryopreservation was first developed in the 1940s by veterinarians and adapted for human sperm in the 1950s. The first pregnancy that used cryopreservation took place in 1954 (1). In fertility practice, clinical indications for cryopreservation include storage of sperm and testicular tissue.

14.3 Indications for storage
Storage of sperm is available in many clinics for the following indications:
- Before potentially sterilising chemotherapy or radiotherapy for cancer (2) or for non-malignant diseases.
- Before surgery that might interfere with fertility (e.g., bladder neck surgery in a younger man or removal of a testicle in a man with testicular malignancy, or before vasectomy or transgender surgery).
- For men with progressive decrease in semen quality as a result of diseases that have an associated risk of subsequent azoospermia (i.e., pituitary macroadenoma, craniopharyngioma, empty sella syndrome, chronic nephropathy, uncontrolled diabetes mellitus, and multiple sclerosis).
- For men with paraplegia when sperm have been obtained by electroejaculation or obtained by penile vibratory stimulation.
- For men with psychogenic anejaculation, after sperm have been obtained either by electroejaculation or a sperm retrieval procedure.
- After gonadotropin treatment has induced spermatogenesis in men with hypogonadotrophic hypogonadism.
- For men with NOA, the chance of finding sperm using micro-TESE is ~50%.

Cryopreservation can be used for sperm collected through TESE, avoiding repeated sperm retrieval procedures and unnecessary hyperstimulation of the female partner.
- In any situation in which sperm have been obtained by a sperm retrieval procedure (e.g., after failed vasectomy reversal, or in some cases of epididymal obstruction not amenable to surgery).
- For storage of donor sperm, because cryopreservation reduces the risk of transmission of infection from sperm donors. According to the European directives 2004/23 EC and 2006/17 EC fresh sperm are no longer to be used for non-partner donations.

14.4 Precautions and techniques

14.4.1 Freezing and thawing process
The cryopreservation techniques currently used are not yet optimal because damage occurs to cells during cryopreservation and prolonged storage. Most damage occurs during freezing and thawing. Major causes of damage during freezing are ice crystal formation and cell dehydration, which disrupt the cell wall and intracellular organelles. Sperm morphology, motility and vitality decrease significantly after thawing, and cryopreservation increases the damage done to sperm DNA (3-6). Further damage can be caused by contamination of samples with microorganisms and high levels of superoxide radicals (7,8). To reduce ice crystal formation, a cryopreservation solution is added before freezing. Various cryopreservation solutions are available commercially, most of which contain varying proportions of glycerol and albumin. After freezing, the
samples are immersed in liquid nitrogen. Several techniques have been developed to try to reduce damage caused by freezing and thawing, including:

- One-step freezing method (9,10): sample is held in the vapour phase for 10 min before being plunged into liquid nitrogen.
- Slow or multi-step method (11): sample is gradually cooled in the vapour phase for approximately 40 min. A programmable automatic freezing machine, which is preset to cool at a rate of 1-10°C/min is used.

The method available depends on the resources of the laboratory. Whichever freezing technique is used, it should be tested using donor sperm and post-thaw examination, and should regularly undergo a quality-control programme.

The likelihood of sperm survival decreases with repeated freezing and thawing. The maximum viable storage time for human sperm is not known. Many laboratory or regulatory authorities apply a storage limit of up to 10 years (12). However, longer storage is sometimes needed (e.g., for a 17-year-old man who has had sperm stored before undergoing chemotherapy for testicular cancer).

14.4.2 Cryopreservation of small numbers of sperm

Standard cryopreservation in straws is an efficient way of storing large numbers of sperm (e.g., for a donor insemination programme). However, in micro-TESE, few sperm might be obtained, and the choice is either to freeze testicular tissue and find sperm after thawing the tissue, or to freeze small numbers of sperm. If sperm are frozen in straws, it can be difficult to find any sperm after thawing. Instead, the sperm should be frozen in a pellet (13) or in a container (14).

14.4.3 Testing for infections and preventing cross-contamination

Sperm storage in straws is used extensively. Large numbers of straws are stored in canisters, with the straws being bathed in a pool of liquid nitrogen. Microbial contamination of the pool of liquid nitrogen results in contamination of the outside of all the straws. The most widely used safeguard is to use so-called high security closed straws. According to the European directives 2004/23 and 2006/17, samples should be tested for hepatitis B and C and human immunodeficiency virus (HIV). In case of non-partner donation, samples are also tested for C. Trachomatis (by NAT) and syphilis, as well as genetics, that is, karyotype and most prevalent genetic disorders in the population to which the non-partner donor belongs.

Until the test results are known, samples must be stored in an individual quarantine vessel (separate storage). If open straws are used (e.g., for vitrification purposes) some laboratories use the additional safeguard of double-wrapping the straws before freezing, although this is more costly. Some centres carry out cytomegalovirus testing and store negative and positive samples separately.

Considerable ethical issues surround the storage of samples before cancer chemotherapy in men who are hepatitis-virus- or HIV-positive. Few clinics have separate storage facilities for HIV-positive samples. However, the success of antiretroviral treatment is increasing the number of HIV-positive men who may wish to store sperm. There is also concern about HIV transmission to children conceived using HIV-positive sperm, because sperm-washing techniques fail in ~5% of cases.

14.4.4 Fail-safe precautions to prevent loss of stored materials

Any laboratory that undertakes long-term storage of human biological materials should have procedures that guard against accidental loss of material caused by storage vessel failure. This is particularly important for sperm stored before potentially sterilising cancer chemotherapy because these patients may not be able to obtain further sperm.

14.4.5 Orphan samples

In malignancy and some other situations, several years might pass before stored samples are required. Inevitably, during this time, the owners of some samples might disappear or die, leaving behind orphan samples for which the owner is no longer contactable. The duty of the laboratory and the legal ownership of these samples can create considerable problems.

14.5 Biological aspects

Cryopreservation induces deterioration of semen quality. After the sample has been thawed, motility (16) and morphology (17,18) are worsened, including mitochondrial acrosomal and sperm tail damage (19). Sperm freezing decreases motility by 31% and mitochondrial activity by 36%, and causes morphological disruption in 37% of sperm (9). Motility is correlated best with IVF capacity of the thawed sample. Further improvement can be achieved by selecting the subpopulation of sperm with the best motility and DNA integrity and freezing these sperm in seminal plasma (13).
14.6 Cryopreservation of testicular stem cells
Spermatogonial stem cell (SSC) preservation and transplantation have been proposed as a promising strategy for fertility preservation in young boys facing SSC loss (20). Since the first publication of SSC transplantation in mice in 1994, remarkable progress has been made towards a clinical application. Cryopreservation protocols for testicular tissue have been developed in animal models, translated to humans, and are already used clinically. Transplantation methods are being used in human testes, and the efficiency and safety of the technique has been evaluated in a mouse model. The application of this technique in humans looks possible, therefore, banking testicular biopsies from prepubertal boys for future stem cell transplantation is being introduced in many centres.

1. INTRODUCTION AND DEFINITION

Definition: male hypogonadism is a clinical syndrome caused by androgen deficiency which may adversely affect multiple organ functions and quality of life (1).

Androgens play a crucial role in the development and maintenance of male reproductive and sexual functions. Low levels of circulating androgens can cause disturbances in male sexual development, resulting in congenital abnormalities of the male reproductive tract. Later in life, this may cause reduced fertility, sexual dysfunction, decreased muscle formation and bone mineralisation, disturbances of fat metabolism, and cognitive dysfunction. Testosterone levels decrease as a process of ageing: signs and symptoms caused by this decline can be considered a normal part of ageing. However, low testosterone levels are also associated with several chronic diseases, and symptomatic patients may benefit from testosterone treatment.

This document presents the European Association of Urology (EAU) guidelines on the diagnosis and treatment of male hypogonadism. These guidelines aim to provide practical recommendations on how to deal with primary low testosterone and ageing-related decline in testosterone in male patients, as well as the treatment of testosterone disruption and deficiencies caused by other illnesses.

1.1 Reference

2. METHODOLOGY

The EAU Male Hypogonadism panel consists of a multidisciplinary group of experts, including urologists specialising in the treatment of infertility, endocrinologists and andrologists. There is a need for ongoing re-evaluation of the information presented in the current guidelines by an expert EAU panel. It must be emphasised that clinical guidelines present the best evidence available to the experts at the time of writing. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when treatment decisions for individual patients are being taken. Guidelines help to focus decisions. Clinical decisions must also take into account patients’ personal values and preferences and their individual circumstances.

2.1 Data identification

The recommendations provided in the current guidelines are based on a systematic literature search performed by the panel members. MedLine, Embase and Cochrane databases were searched to identify original articles and review articles. The controlled vocabulary of the Medical Subject Headings (MeSH) database was used alongside a ‘free-text’ protocol, combining ‘male hypogonadism’ with the terms ‘diagnosis’, ‘epidemiology’, ‘investigations’, ‘treatment’, ‘testosterone’, ‘androgens’ and ‘hypogonadism’.

All articles published before January 2012 were considered for review. The expert panel reviewed these records and selected articles with the highest level of evidence in accordance with a rating schedule adapted from the Oxford Centre for Evidence-Based Medicine levels of evidence.

2.2 Levels of evidence and grades of recommendation

References used in the text have been assessed according to their level of scientific evidence (Table 1). Guideline recommendations have been graded (Table 2) in accordance with the Oxford Centre for Evidence-Based Medicine levels of evidence (LE) (1). The aim of grading recommendations (GR) is to provide transparency between the underlying evidence and the recommendation given.

</tr>
</tbody>
</table>
Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.

Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.

* Modified from Sackett et al. (1).

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and the grade of recommendation. The availability of RCTs may not necessarily translate into a grade A recommendation if there are methodological limitations or disparities in the published results. Conversely, an absence of high-level evidence does not necessarily preclude a grade A recommendation if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the reader. Whenever this occurs, it has been clearly indicated in the text with an asterisk as ‘upgraded based on panel consensus’. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned (2-4).

The EAU Guidelines Office does not perform cost assessments, nor can they address local/national preferences in a systematic fashion. However, whenever such data are available, the expert panels will include the information.

### 2.3 Publication history
The present male hypogonadism guidelines are a new publication that underwent a blinded peer-review process before publication. The standard procedure will be an annual assessment of newly published literature in this field, guiding future updates. An ultra-short reference document is published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

3. EPIDEMIOLOGY

3.1 Introduction
Androgen deficiency increases with age; an annual decline in circulating testosterone of 0.4-2.0% has been reported (1,2). In middle-aged men, the incidence was found to be 6% (3). It is more prevalent in older men, in men with obesity, those with co-morbidities, and in men with a poor health status.

3.2 Role of testosterone for male reproductive health
Androgens, which are produced by the testis and the adrenal glands, play a pivotal role in male reproductive and sexual function. Androgens are also crucial for the development of male reproductive organs, such as the epididymis, vas deferens, seminal vesicle, prostate and penis. In addition, androgens are needed for puberty, male fertility, male sexual function, muscle formation, body composition, bone mineralisation, fat metabolism, and cognitive functions (4).

3.3 Physiology
Male sexual development starts between the 7th and 12th week of gestation. The undifferentiated gonads develop into a foetal testis through expression of the sex-determining region Y gene (SRY), a gene complex located on the short arm of the Y chromosome (5). The foetal testis produces two hormones: testosterone and anti-Müllerian hormone (AMH).

Testosterone is needed for the development of the Wolffian ducts, resulting in formation of the epididymis, vas deferens and seminal vesicle. AMH activity results in regression of the Müllerian ducts (Figure 1). Under the influence of intratesticular testosterone, the number of gonocytes per tubule increases threefold during the foetal period (6).

In addition, testosterone is needed for development of the prostate, penis and scrotum. However, in these organs testosterone is converted into the more potent metabolite dihydrotestosterone (DHT) by the enzyme 5α-reductase (7). The enzyme is absent in the testes, which explains why 5α-reductase inhibitors do not have a marked effect on spermatogenesis. Testosterone and DHT are required for penile growth, both activating the androgen receptor. The androgen receptor (AR) in the penis disappears after puberty, thus preventing further growth of the penis (8).

Intratesticular testosterone is needed to maintain the spermatogenic process and to inhibit germ cell apoptosis (9). The seminiferous tubules of the testes are exposed to concentrations of testosterone 25-100 times greater than circulating levels. Suppression of gonadotrophins (e.g. through excessive testosterone abuse) results in a reduced number of spermatozoa in the ejaculate and hypospermatogenesis (10). Complete inhibition of intratesticular testosterone results in full cessation of meiosis up to the level of spermatids (11,12). Testosterone does not appear to act directly on the germ cells, but functions through the Sertoli cells by expression of the AR and influencing the seminiferous tubular microenvironment (12).

Testosterone can also be metabolised into oestradiol by aromatase, present in fatty tissue, the prostate and bone. Oestradiol is essential for bone mineralisation, also in men (13).

The production of testosterone is controlled by luteinizing hormone (LH) from the pituitary gland. Immediately after birth, serum testosterone levels reach adult concentrations over several months. Thereafter and until puberty, testosterone levels are low, thus preventing male virilisation. Puberty starts with the production of gonadotrophins, initiated by GnRH secretion from the hypothalamus and resulting in testosterone production, male sexual characteristics and spermatogenesis (14). Figure 1 shows the development of the male reproductive system.

3.4 The androgen receptor
Testosterone exerts its action through the androgen receptor (AR), located in the cytoplasm and nucleus of target cells. During the foetal period, testosterone increases the number of androgen receptors by increasing the number of cells with the AR, but also by increasing the number of ARs in each individual cell (8,13).

The AR gene is located on the X chromosome (Xq 11-12): defects and mutations in the AR gene can result in male sexual maldevelopment, which may cause testicular feminisation or low virilisation. Less severe mutations in the AR gene may cause mild forms of androgen resistance and male infertility (15). In exon 1 of the gene, the transactivation domain consists of a trinucleotide tract (cytosine–adenine–guanine [CAG-repeats]) of variable length. Androgen sensitivity may be influenced by the length of the CAG repeats in exon 1 of the AR gene (15). The AR CAG repeat length is inversely correlated with serum total and bioavailable testosterone in ageing men. Shorter repeats have been associated with an increased risk for prostate disease, and longer repeats with reduced androgen action in several tissues (16). CAG repeat number may influence androgenic phenotypical effects, even in case of normal testosterone levels (17).
Conclusion
Testosterone is essential for normal male development.

4. AETIOLOGY (PRIMARY AND SECONDARY FORMS AND LATE-ONSET HYPOGONADISM)

4.1 Introduction
Hypogonadism results from testicular failure, or is due to the disruption of one or several levels of the hypothalamic-pituitary-gonadal axis (Table 3).

Male hypogonadism can be classified in accordance with disturbances at the level of:
- the hypothalamus and pituitary (secondary hypogonadism);
- the testes (primary hypogonadism);
- the hypothalamus/pituitary and gonads (late-onset hypogonadism);
- androgen target organs (androgen insensitivity/resistance).

4.2 Male hypogonadism of hypothalamic-hypopituitary origin (secondary hypogonadism)
Central defects of the hypothalamus or pituitary cause secondary testicular failure. Identifying secondary hypogonadism is of clinical importance, as it can be a consequence of pituitary pathology (including prolactinomas) and can cause infertility, which can be restored by hormonal stimulation in most patients with secondary hypogonadism.
The most relevant forms of secondary hypogonadism are:

- **Hyperprolactinemia (HP)**, caused by prolactin-secreting pituitary adenomas (prolactinomas) (microprolactinomas < 10 mm in diameter vs. macroprolactinomas) or drug-induced (by dopamine-antagonistic effects of substances such as phenothiazine, imipramine and metoclopramide); additional causes may be chronic renal failure or hypothyroidism.
- **Isolated hypogonadotrophic hypogonadism (IHH)** (formerly termed idiopathic hypogonadotrophic hypogonadism, IHH).
- **Kallmann syndrome** (hypogonadotrophic hypogonadism with anosmia, genetically determined, prevalence one in 10,000 males).

These disorders are characterised by disturbed hypothalamic secretion or action of GnRH, as a pathophysiology common to the diseases, resulting in impairment of pituitary LH and FSH secretion. An additional inborn error of migration and homing of GnRH-secreting neurons results in Kallmann syndrome (1,2).

The most important differential diagnosis is the constitutional delay of puberty, as it is the most common cause of delayed puberty (pubertas tarda) with a prevalence of one in 40 in males, caused by a delayed increase in pulsatile GnRH secretion with an autosomal-dominant pattern of inheritance (3). Other rare forms of secondary hypogonadism are listed in Table 3.

### 4.3 Male hypogonadism of gonadal origin (primary hypogonadism)

Primary testicular failure results in low testosterone levels, impairment of spermatogenesis and elevated gonadotrophins. The most important clinical forms of primary hypogonadism are Klinefelter syndrome (one in 500 males) and testicular tumours (12 in 100,000 males).

- **Klinefelter syndrome** affects 0.2% of the male population. It is the most frequent form of male hypogonadism and the most common numerical chromosomal aberration, with 47,XXY in 90% of cases (4). It arises due to non-disjunction during paternal or maternal meiotic division of germ cells (5).
- **Testicular tumours** are the most frequent type of cancer in young males during reproductive age. Risk factors are contralateral germ cell cancer, maldescended testes, gonadal dysgenesis, infertility and familial germ cell cancer. Twenty-five per cent of patients suffer from testosterone deficiency after treatment (6-8).

Other reasons for primary testicular failure are summarised in Table 4.

### 4.4 Male hypogonadism due to mixed dysfunction of hypothalamus/pituitary and gonads

Combined primary and secondary testicular failure results in low testosterone levels, impairment of spermatogenesis and variable gonadotrophin levels. Gonadotrophin levels depend on the predominant primary or secondary failure. This form was named late-onset hypogonadism some years ago (9,10).

### 4.5 Male hypogonadism due to defects of androgen target organs

These forms are primarily rare defects and will not be further discussed in detail in these guidelines. There are androgen receptor defects with complete, partial and minimal androgen insensitivity syndrome; Reifenstein syndrome; bulbospinal muscular atrophy (Kennedy disease); as well as 5α-reductase deficiency (for a review, see Nieschlag et al. 2010) (11).

The classification of hypogonadism has therapeutic implications. In patients with secondary hypogonadism, hormonal stimulation with hCG and FSH or alternatively GnRH can restore fertility in most cases (12,13). However, fertility options for males with primary hypogonadism are limited. Detailed evaluation may for example detect pituitary tumours, systemic disease, or testicular tumours.

Combined forms of primary and secondary hypogonadism can be observed in older men, with a concomitant age-related decline in testosterone levels resulting from defects in testicular as well as hypothalamic-pituitary function. A significant percentage of men over the age of 60 years have serum testosterone levels below the lower reference limits in young adults (14-18).

</tr>
</tbody>
</table>
The two forms of hypogonadism have to be differentiated, as this has implications for patient evaluation and treatment and makes it possible to identify patients with associated health problems and infertility.

### References

5. **DIAGNOSIS**

5.1 **Introduction**

Hypogonadism is diagnosed on the basis of persistent symptoms and signs related to androgen deficiency and assessment of consistently low testosterone levels (at least on two occasions) with a reliable method (1-5).

5.2 **Clinical symptoms**

Low levels of circulating androgens may be associated with signs and symptoms (Table 5).

---

FSH = follicle-stimulating hormone; GnRH = Gonadotrophin-releasing hormone; LH = luteinizing hormone.

The most prevalent symptoms of male hypogonadism in ageing men are reduced sexual desire and sexual activity, erectile dysfunction, and hot flushes (1).

Symptoms and signs of androgen deficiency vary depending on age of onset, duration and the severity of the deficiency. Reference ranges for the lower normal level of testosterone (percentile 2.5) have recently been compiled from three large community-based samples, suggesting a cut-off of 12.1 nmol/L for total serum testosterone and for calculated free testosterone 243 pmol/L, to distinguish between normal levels and levels possibly associated with deficiency (6). Symptoms suggesting the presence of hypogonadism (1,7) are summarised in Table 5.

In men aged 40-79 years, the threshold for total testosterone was 8 nmol/L for decreased frequency of sexual thoughts, 8.5 nmol/L for erectile dysfunction, 11 nmol/L for decreased frequency of morning erections and 13 nmol/L for diminished vigour (8). The strongest predictor for hypogonadism in this age group was three sexual symptoms (decreased sexual thoughts, weakened morning erections, erectile dysfunction) and either a total testosterone level of < 8 nmol/L or serum testosterone in the range of 8-11 nmol/L and free testosterone < 220 pmol/L. These data are based on serum samples taken in the morning, when levels are highest and best reproducible (9).

Hypogonadism may be more subtle and not always evident by low testosterone levels. For example, men with primary testicular damage often have normal testosterone levels but high LH: this could be considered a subclinical or compensated form of hypogonadism. The clinical consequences of an isolated elevation of LH is not clear yet, but potentially these men may already have signs or symptoms of hypogonadism or will become hypogonadal in the future.

To differentiate between primary and secondary forms of hypogonadism and to clarify late-onset hypogonadism determination of LH serum levels is required. Both LH and testosterone serum levels should be analysed twice.

5.3 History-taking and questionnaires

Symptoms of hypogonadism are listed in Table 5 and should be addressed during history-taking. Early onset of hypogonadism causes a lack of or minimal pubertal development, lack of development of secondary sex characteristics, possibly eunuchoid body proportions and a high-pitched voice. These signs and symptoms strongly suggest hypogonadism. Postpubertal development of hypogonadism causes a loss of androgen-dependent functions and symptoms that may have other etiological backgrounds than low testosterone levels. Published questionnaires are unreliable and have low specificity, while their sensitivity is high, and are not effective for case-finding (10-13). It is important to assess and exclude systemic illnesses, signs of malnutrition and malabsorption, as well as ongoing acute disease. Pharmacological treatments with corticosteroids, abuse of drugs such as marijuana, opiates and alcohol and previous treatment or use of testosterone or abuse of anabolic steroids should also be included in history-taking.
5.4 Physical examination
Assessment of body mass index (BMI), the waist-hip ratio (or sagittal abdominal diameter), body hair, male-pattern hair loss, presence of gynaecomastia and testicular size (measured with an orchidometer or ultrasound [US]) and a structural examination of the penis as well as a digital rectal examination (DRE) of the prostate should be included.

Conclusion

The diagnosis of male hypogonadism is based on symptoms and signs of androgen deficiency, together with consistently low serum testosterone levels.

6. **CLINICAL CONSEQUENCES OF HYPOGONADISM**

6.1 **Introduction**
The clinical consequences of hypogonadism are determined by the age of onset and the severity of hypogonadism.

6.2 **Foetal androgen deficiency**
During the first 14 weeks of gestation, the presence of testosterone is crucial for normal virilisation of the external male genitalia. Androgen deficiency or androgen resistance due to deficient androgen receptor
function during this stage of life may result in abnormal genital development, ranging from hypospadias to female external genitalia with intra-abdominal testis. Frequently, patients with disorders of sexual development are diagnosed at an early age because of clearly abnormal external genitalia. However, patients at both ends of the phenotypic spectrum may go unnoticed in childhood and are diagnosed during puberty because of delayed pubertal development in phenotypic men or primary amenorrhea in XY women.

6.3 Prepubertal onset of androgen deficiency
At the start of puberty, rising gonadotrophin levels result in increasing testicular volume and the activation of spermatogenesis and testosterone secretion. During puberty, rising testosterone levels result in the development of male secondary sex characteristics, comprising deepening of the voice, development of terminal body hair, stimulation of hair growth in sex-specific regions, facial hair, increasing penile size, increase in muscle mass and bone size and mass, growth spurt induction and eventually closing of the epiphyses. In addition, testosterone has explicit psychosexual effects, including increased libido.

Delayed puberty is defined as an absence of testicular enlargement at the age of 14. As this is a ‘statistical’ definition, based on reference ranges for the onset of puberty in the normal population, delayed puberty does not necessarily indicate the presence of a disease. In cases of severe androgen deficiency, the clinical picture of prepubertal-onset hypogonadism is evident (Table 6) and diagnosis and treatment are fairly straightforward. The major challenge in younger individuals with presumed idiopathic hypogonadotropic hypogonadism is to differentiate the condition from a constitutional delay in puberty and to determine when to start androgen treatment. In milder cases of androgen deficiency, such as are seen in patients with Klinefelter syndrome, pubertal development can be incomplete or delayed, resulting in a more subtle phenotypic picture. In these patients, several clues may lead to a diagnosis of hypogonadism. These include: small testes, (a history of) cryptorchidism, gynaecomastia, sparse body hair, eunuchoid habitus, low bone mass and subfertility (1).

6.4 Late-onset hypogonadism
Definition: Late-onset hypogonadism is defined as hypogonadism in a person who has had normal pubertal development and as a result developed normal male secondary sex characteristics.

Depending on the underlying cause of hypogonadism, the decline in gonadal function may be gradual and partial. The resulting clinical picture may be variable, and the signs and symptoms may be obscured by the physiological phenotypic variation. Symptoms that have been associated with late-onset androgen deficiency include: loss of libido, erectile dysfunction, sarcopenia, low bone mass, depressive thoughts, fatigue, loss of vigour, erectile dysfunction, loss of body hair, hot flushes and reduced fertility (Table 7). Most of these symptoms have a multifactorial aetiology, are reminiscent of normal aging and can also be found in men with completely normal testosterone levels (2). As a result, signs and symptoms of adult-onset hypogonadism may be non-specific, and confirmation of a clinical suspicion by hormonal testing is mandatory. For most of the symptoms mentioned above, the probability of their presence increases with lower plasma testosterone levels. Most studies indicate a threshold level below which the prevalence of symptoms starts to increase (3,4). This threshold level is near the lower level of the normal range for plasma testosterone levels in young men, but there appears to be a wide variation between individuals, and even within one individual the threshold level...
may be different for different target organs.

7. **INDICATIONS AND CONTRAINDICATIONS FOR TREATMENT**

Testosterone treatment aims to restore testosterone levels to the physiological range in men with consistently low levels of serum testosterone and associated symptoms of androgen deficiency. The aim is to improve quality of life, sense of well-being, sexual function, muscle strength and bone mineral density. Table 8 highlights the main indications for testosterone treatment. Table 9 lists the main contraindications against testosterone therapy.

8. **BENEFITS OF TREATMENT**

Testosterone replacement therapy (TRT) provides several benefits in relation to body composition, metabolic control and psychological and sexual parameters. Randomised trials have shown a correlation between restored physiological testosterone levels, muscle mass and strength measured as leg press strength and quadriceps muscle volume (1-4). Similar positive results have been reported in meta-analyses evaluating the role of exogenous testosterone in relation to bone mineral density: it is evident that testosterone therapy improves mineral density at the lumbar spine, producing a reduction in bone resorption markers. The available trials failed to demonstrate a similar effect at the femoral neck (4-6). Body composition is influenced by testosterone therapy in hypogonadal men, with a consequent decrease in fat mass and an increase in lean body mass (4). Several studies based on experience with testosterone undecanoate have demonstrated a significant reduction in trunk and waist fat, with a clear decrease in waist size (7,8). In the same trials, testosterone undecanoate administration was associated with an improvement in body weight, body mass index and lipid profile after 3 months of therapy. Testosterone replacement therapy has positive effects on glycaemic and lipid control, insulin resistance and visceral adiposity in hypogonadal men with impaired glucose tolerance and lipid profiles, with a consequent decrease in the cardiovascular risk (9). Benefits on libido, erection and ejaculation have been reported in several retrospective studies and case reports. In a multicentre prospective study, Moon et al. (10) reported a significant increase in the International Index of Erectile Function (IIEF) score for sexual desire, intercourse satisfaction and overall satisfaction starting 6 weeks after the beginning of treatment. Testosterone replacement therapy has also shown encouraging results in several case reports in which satisfactory sexual intercourse was reported after at least 3 months from therapy induction in hypogonadal men suffering from veno-occlusive erectile dysfunction (4,11). Significant improvement in depressive symptoms in men treated with testosterone undecanoate is reported in a randomised trial, while benefits in relation to the cognitive spectrum have been reported in studies with a lower impact (12,13).

**Conclusion**

Benefits including a reduction in BMI and waist size and improved glycaemic control and lipid profile are observed in hypogonadal men receiving TRT.
Testosterone replacement therapy is recommended in patients with:

- A decline in muscle mass and strength
- Reduced bone mineral density at the lumbar spine
- Decreased libido and erection

9. CHOICE OF TREATMENT

9.1 Introduction
The aim of TRT is to restore physiological testosterone levels in hypogonadal men (1). During TRT, periodic observation of the serum concentration of the hormone and its metabolites is recommended in order to alleviate treatment-related side effects (1). Several preparations are available, which differ in the route of administration and pharmacokinetics, and the selection should be a joint decision by both the patient and the physician (2). Short-acting preparations may be preferred to long-acting depot administration in the initial treatment phase, so that any adverse events that may develop can be observed and treatment can be discontinued if needed (3).

Testosterone replacement therapy is safe and effective and the agents are available as oral preparations, intramuscular injections and transdermal gel or patches (4).

9.2 Preparations

9.2.1 Testosterone undecanoate
Testosterone undecanoate is the most widely used and safest oral delivery system. It rarely causes a rise in testosterone levels above the mid-range and it is therefore infrequently associated with side effects (1). In oral administration, resorption depends on simultaneous intake of fatty food.

Testosterone undecanoate is also available as a long-acting intramuscular injection (with intervals of up to 3 months). This long period of action ensures a normal testosterone serum concentration for the entire period, but the relatively long wash-out period may cause problems if complications appear (5).

9.2.2 Testosterone cypionate and enanthate
Testosterone cypionate and enanthate are available as short-acting intramuscular delivery systems (with intervals of 2-3 weeks) and represent safe and valid preparations. However, these preparations may cause fluctuations in serum testosterone from high levels to subnormal levels, and they are consequently associated with periods of well-being alternating with periods of unsatisfactory clinical response (6,7).

9.2.3 Transdermal testosterone
Transdermal testosterone preparations are available as skin patches or gel. They provide a uniform and normal serum testosterone level for 24 hours (daily interval). Common side effects consist of skin irritation at the site of application (patches) and risk of interpersonal transfer if appropriate precautions are not taken (gel) (8,9).

9.2.4 Sublingual and buccal testosterone
Sublingual and buccal testosterone tablets are effective and well-tolerated delivery systems that can provide a rapid and uniform achievement of a physiological testosterone level with daily administration (10,11).

9.2.5 Subdermal depots
Subdermal depots need to be implanted every 5-7 months and offer a long period of action without significant serum fluctuation of the testosterone level. The risk with this kind of delivery system lies in infections and extrusions, which may occur in up to 10% of cases (1,12,13).

9.3 Hypogonadism and fertility issues
Exogenous testosterone reduces endogenous testosterone production by negative feedback on the hypothalamic-pituitary-gonadal axis. If hypogonadism coincides with fertility issues, hCG treatment should be considered.

Human chorionic gonadotrophin (hCG) stimulates testosterone production of Leydig cells. Its administration should be restricted to patients with secondary hypogonadism, if fertility issues are important. Normal physiological serum levels can be achieved with a standard dosage of 1500-5000 IU administered intramuscularly or subcutaneously twice weekly. In patients with secondary hypogonadism, hCG treatment is combined with FSH treatment (usually 150 IU three times weekly i.m. or s.c.) to induce spermatogenesis.

In patients with secondary hypogonadism and fertility issues, and in selected cases of primary hypogonadism, hCG treatment can be chosen to support endogenous testosterone production for the period of infertility treatment. The dosage has to be adjusted individually to prevent suppression of FSH serum levels. hCG treatment has higher costs than testosterone treatment. There is insufficient information about the therapeutic and adverse effects of long-term hCG treatment. This type of treatment can therefore not be recommended for male hypogonadism, except in patients in whom fertility treatment is an issue.

10. RISK FACTORS IN TESTOSTERONE TREATMENT

10.1 Introduction
Physicians are often reluctant to offer TRT, especially in elderly men, due to the potential risk of this form of treatment (1). The most common doubts are associated with the possible consequences for prostatic and breast tissues, the cardiovascular system and sleep apnoea.

10.2 Male breast cancer
Male breast cancer is a rare disease, with an incidence of less than 1% of all male cancers (2). The incidence is higher in men with Klinefelter syndrome. Testosterone treatment is contraindicated in men with a history of breast cancer (3). An association between TRT and the development of breast cancer is not supported by strong evidence, although there have been some reports based on small numbers of patients (4).

10.3 Prostate cancer
Prostate cancer growth may be influenced by testosterone. Studies have reported that hypogonadism is associated with a lower incidence of prostate cancer, but if prostate cancer occurs in hypogonadal men, it is usually at an advanced stage and with a higher Gleason score (5,6). Randomised controlled trials support
the hypothesis that TRT does not result in changes in prostatic histology, nor in a significant increase in intraprostatic testosterone and DHT (7,8). The most recent studies indicate that testosterone therapy does not increase the risk of prostate cancer (7-10), but long-term follow-up data are not yet available. A meta-analysis showed a higher (but not statistically significant) percentage of prostate events in middle-aged and older men receiving TRT (11). In view of these observations, PSA testing and digital examination of the prostate before and during therapy are highly recommended (11).

Testosterone therapy is clearly contraindicated in men with prostate cancer. A topic currently under debate involves the use of TRT in hypogonadal men with a history of prostate cancer and no evidence of active disease. So far, only studies with limited numbers of patients and relatively short follow-up periods are available, and these indicate no increased risk for recurrent prostate cancer. No randomised and placebo-controlled trials are available yet to document the long-term safety of the treatment in these patients (12). Men who have been surgically treated for localised prostate cancer and who are currently without evidence of active disease (i.e. measurable PSA, abnormal rectal examination, evidence of bone/visceral metastasis) and showing symptoms of testosterone deficiency can be cautiously considered for TRT, although this approach is still an ‘off-label’ treatment (13,14). In these patients, treatment should be restricted to patients with a low risk for recurrent prostate cancer (pre-surgery Gleason < 8; pT1-2; PSA < 10 ng/mL). Therapy should not start before 1 year of follow-up after surgery and there should be no PSA recurrence (13-15). Patients who have undergone brachytherapy or external-beam radiotherapy (EBRT) for low-risk prostate cancer can also be cautiously treated with TRT in case of hypogonadism, with close monitoring for prostate cancer recurrence (14-16).

10.4 Cardiovascular diseases
Testosterone treatment is not related to the development of de novo cardiovascular events (17,18). Caution, however, should be used in men with existing cardiovascular diseases, since an increase in red blood cells is a common side effect of testosterone. Haemoglobin and haematocrit measurements are recommended before treatment and periodically thereafter (9,11,19). Patients with erythrocytosis and serious congestive heart failure (NYHA classes III-IV) are at risk of developing cardiovascular deterioration, and testosterone therapy should be discontinued until the resolution of congestive heart failure (9). Cardiovascular adverse events are more frequent in patients with multiple co-morbidities and with limited physical activity (19).

10.5 Obstructive sleep apnoea
There is no consistent evidence correlating TRT with obstructive sleep apnoea (OSA). There is also no evidence that TRT can result in the onset or worsening of the condition (20).

### Conclusions

| Case reports and small cohort studies point to a possible correlation between TRT and the onset of breast cancer, but there is as yet a lack of strong evidence for this relationship. | 3 |
| Randomised controlled trials support the hypothesis that TRT does not result in changes in prostatic histology. | 1b |
| Testosterone therapy is not related to the development of de novo cardiovascular events. | 1a |
| There is no evidence for a relationship between TRT and OSA. | 3 |

### Recommendations

| Haematological, cardiovascular, breast and prostatic assessment should be performed before the start of treatment. | 1a | A |
| Haematocrit and haemoglobin monitoring, PSA and digital rectal examination of prostate and breast examination are recommended assessments during TRT therapy. | 1a | A |
| In patients operated on for localised prostate cancer, testosterone therapy should not start before 1 year of follow-up without PSA recurrence has been completed. | 4 | B |

*PSA = prostate-specific antigen; TRT = testosterone replacement therapy*

11. MONITORING OF PATIENTS RECEIVING TESTOSTERONE REPLACEMENT THERAPY

11.1 Introduction
Regular follow-up is needed in patients receiving testosterone therapy, as potentially androgen-dependent symptoms and conditions may occur as a result of TRT. The side effects of TRT are limited, but their incidence and clinical relevance is as yet unclear.

The primary aim of TRT is to alleviate the clinical symptoms of testosterone deficiency. Careful monitoring of changes in the clinical manifestations of testosterone deficiency should therefore be an essential part of every follow-up visit. Effects of TRT on sexual interest may already appear after 3 weeks of treatment, and reach a plateau at 6 weeks (1). Changes in erectile function and ejaculation may require up to 6 months (1). Effects on quality of life, and also on depressive mood, may become detectable within 1 month, but the maximum effect may take longer (1).

11.2 Testosterone level
There are as yet insufficient data to define optimal serum levels of testosterone during TRT. Expert opinion suggests that TRT should restore the serum testosterone level to the mid-normal range of specific age groups of men, which is usually sufficient to alleviate various manifestations of hormone deficiency. An optimal monitoring schedule for serum testosterone level is also dependent on the formulation of TRT used (LE: 4; GR: C).

11.3 Bone density
Bone mineral density (BMD) should be monitored only in men whose BMD was abnormal before initiation of TRT. An increase in lumbar spine BMD may already be detectable after 6 months of TRT and may continue for 3 more years (1).

11.4 Haematocrit
It is important to use only minimal or no venous occlusion when taking a blood sample for haematocrit measurements (2). Elevated haematocrit is the most frequent side effect of TRT. The clinical significance of a high haematocrit level is unclear, but it may be associated with hyperviscosity and thrombosis (3). The effect of erythropoiesis may become evident at 3 months and peaks at 12 months (1).

11.5 Prostate safety
Testosterone replacement therapy results in a marginal increase in PSA and prostate volume, plateauing at 12 months (1). Previous fears that TRT might increase the risk of prostate cancer have been contradicted by a number of meta-analyses (4-7). However, there are insufficient long-term data available to conclude that there is safety from prostate cancer with TRT.

11.6 Cardiovascular system
Testosterone replacement therapy is not associated with the development of any unsafe cardiovascular events, and special monitoring in this respect is not needed (7,8). There has been one study (9) indicating that testosterone therapy in older men with a high prevalence of chronic diseases may result in a higher risk of cardiovascular adverse events. These patients may need individualised monitoring schemes.

1. INTRODUCTION

1.1 Background
Urinary tract infections (UTIs) are among the most prevailing infectious diseases with a substantial financial burden on society. In the USA, UTIs are responsible for over 7 million physician visits annually (1). Approximately 15% of all community-prescribed antibiotics in the USA are dispensed for UTI (2) and data from some European countries suggest a similar rate (3). In the US, UTIs account for more than 100,000 hospital admissions annually, most often for pyelonephritis (1). These data do apparently not account for complicated UTI associated with urological patients, the prevalence of which is not known. UTIs represents at least 40% of all hospital acquired infections and are, in the majority of cases, catheter associated (4). Bacteriuria develops in up to 25% of patients who require a urinary catheter for one week or more with a daily risk of 5-7% (5,6). The recent Global Prevalence Infection in Urology (GPIU) studies have shown that 10-12% of patients hospitalised in urological wards have a healthcare-associated infection (HAI). The strains retrieved from these patients are even more resistant (7).

1.2 Bacterial resistance development
The present state of microbial resistance development is alarming (8). The use of antibiotics in the different countries of Europe mirrors the global increase in resistant strains (8). The presence of extended-spectrum β-lactamase (ESBL) producing bacteria showing resistance to most antibiotics, except for the carbapenem group, is steadily increasing in the population (10). Even more alarming are the recent reports from all continents of faecal bacteria carrying the ESBL-\text{carba} \text{enzyme} (i.e New-Delhi metallo-β-lactamase NDM-1) making them resistant to all available antibiotics including the carbapenem group.

Particularly troublesome is the increasing resistance to broad-spectrum antibiotics such as fluoroquinolones and cephalosporins due to an overconsumption of these two groups and the parallel development of co-resistance to other antibiotics (collateral damage) (11). This development is a threat for patients undergoing urological surgery in general and men subjected to prostate biopsy in particular.

An urgent and strong grip on this threatening development is thus required. With only a few new antibiotics expected in the coming 5 to 10 years, prudent use of available antibiotics is the only option to delay the development of resistance (9) and the urological community has a responsibility to participate in this combat. It is essential to consider the local microbial environment and resistance pattern as well as each individual patient’s risk factors for harbouring resistant microbes.

Bacterial resistance development is a threat
- To treatment of UTI
- Prophylaxis in urological surgery

There is a direct correlation between the use of antibiotics and resistance development

There is an urgent need for combating resistance development by a prudent use of available antibiotics

1.3 The aim of the guidelines
It is the ambition of the present guidelines to provide both urologist and physicians from other medical specialities with evidence-based guidance regarding the treatment and prophylaxis of UTI. These guidelines cover male and female UTIs, male genital infections and special fields such as UTI in paediatric urology, immunosuppression, renal insufficiency and kidney transplant recipients. Much attention is given to antibiotic prophylaxis, aiming to reduce the overuse of peri-operative prophylactic antibiotics. High quality clinical research using strict internationally recognised definitions and classifications as presented in this section are encouraged.

1.4 Pathogenesis of UTIs
Microorganisms can reach the urinary tract by haematogenous or lymphatic spread, but there is abundant clinical and experimental evidence to show that the ascent of microorganisms from the urethra is the most common pathway that leads to a UTI, especially organisms of enteric origin (e.g. E. coli and other Enterobacteriaceae). This provides a logical explanation for the greater frequency of UTIs in women than in men, and for the increased risk of infection following bladder catheterisation or instrumentation. A single insertion of a catheter into the urinary bladder in ambulatory patients results in urinary infection in 1-2% of cases. Indwelling catheters with open-drainage systems result in bacteriuria in almost 100% of cases within 3-4 days. The use of a closed-drainage system, including a valve to prevent retrograde flow, delays the onset of infection, but ultimately does not prevent it. It is thought that bacteria migrate within the mucopurulent space between the urethra and catheter, and that this leads to the development of bacteriuria in almost all patients within about 4 weeks.
Haematogenous infection of the urinary tract is restricted to a few relatively uncommon microbes, such as *Staphylococcus aureus*, *Candida* sp., *Salmonella* sp. and *Mycobacterium tuberculosis*, which cause primary infections elsewhere in the body. *Candida albicans* readily causes a clinical UTI via the haematogenous route, but is also an infrequent cause of an ascending infection if an indwelling catheter is present, or following antibiotic therapy.

The concept of bacterial virulence or pathogenicity in the urinary tract infers that not all bacterial species are equally capable of inducing infection. The more compromised the natural defence mechanisms (e.g. obstruction, or bladder catheterisation), the fewer the virulence requirements of any bacterial strain to induce infection. This is supported by the well-documented *in vitro* observation that bacteria isolated from patients with a complicated UTI frequently fail to express virulence factors. The virulence concept also suggests that certain bacterial strains within a species are uniquely equipped with specialised virulence factors, e.g. different types of pili, which facilitate the ascent of bacteria from the faecal flora, introitus vaginae or periurethral area up the urethra into the bladder, or less frequently, allow the organisms to reach the kidneys to induce systemic inflammation.

1.5 Microbiological and other laboratory findings

The number of bacteria is considered relevant for the diagnosis of a UTI. In 1960, Kass developed the concept of significant bacteriuria (≥ 10⁵ cfu/mL) in the context of pyelonephritis in pregnancy (12). Although this concept introduced quantitative microbiology into the diagnosis of infectious diseases, and is therefore still of general importance, it has recently become clear that there is no fixed bacterial count that is indicative of significant bacteriuria, which can be applied to all kinds of UTIs and in all circumstances. As described in Appendix 16.1, the following bacterial counts are clinically relevant:

- ≥ 10³ cfu/mL of uropathogens in a mid-stream sample of urine (MSU) in acute uncomplicated cystitis in women.
- ≥ 10⁴ cfu/mL of uropathogens in an MSU in acute uncomplicated pyelonephritis in women.
- ≥ 10⁵ cfu/mL of uropathogens in an MSU in women, or ≥ 10⁴ cfu/mL uropathogens in an MSU in men, or in straight catheter urine in women, in a complicated UTI.

In a suprapubic bladder puncture specimen, any count of bacteria is relevant. The problem of counting low numbers, however, has to be considered. If an inoculum of 0.1 mL of urine is used and 10 identical colonies are necessary for statistical reasons of confidence, then in this setting, the lowest number that can be counted is 100 cfu/mL of uropathogens. Asymptomatic bacteriuria is diagnosed if two cultures of the same bacterial strain (in most cases the species only is available), taken ≥ 24 h apart, show bacteriuria of ≥ 10⁵ cfu/mL of uropathogens.

It is obvious that methods of urine collection and culture, as well as the quality of laboratory investigations, may vary. Two levels of standard must therefore be used for the management of patients. A basic standard level is necessary for routine assessment, whereas a higher standard level is required for scientific assessment and in special clinical circumstances, e.g. fever of unknown origin in immunocompromised patients. In research, the need for a precise definition of sampling methods, such as the time that urine is kept in the bladder, must be recognised, and these parameters carefully recorded.

In clinical routine assessment, a number of basic criteria must be looked at before a diagnosis can be established, including:

- clinical symptoms;
- results of selected laboratory tests (blood, urine or expressed prostatic secretion [EPS]);
- evidence of the presence of microorganisms by culturing or other specific tests;
- most of these investigations can today be performed in any laboratory.

It has to be considered, however, that microbiological methods and definitions applied must follow accepted standards with regard to specimen transport, pathogen identification, and antimicrobial susceptibility testing. These methods and microbiological definitions may vary between countries and institutions. One example is the breakpoints for classification of pathogen susceptibility. It is important to report not only the results, but also which methods and standards were applied, such as the European Committee for Antimicrobial Susceptibility Testing (EUCAST) (13,14), or the National Committee for Clinical Laboratory Standards (NCCLS) (15). Mixing results obtained by different methods, e.g. rates of bacterial resistance, can be problematic and requires careful interpretation. Histological investigation sometimes shows the presence of non-specific inflammation. Only in some cases, such findings (e.g. prostatitis in patients who have elevated levels of prostate-specific antigen [PSA]) might help determine the appropriate treatment, whereas in more specific inflammation, such as tuberculosis and actinomycosis, histology can be diagnostic. In general, however, histological findings usually contribute very little to the treatment decisions.
1.6 Methodology

The EAU Urological Infections guidelines panel consists of a group of urologists, specialised in the treatment of UTIs. It must be emphasised that clinical guidelines present the best evidence available to the experts at the time of writing. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when treatment decisions for individual patients are being taken. Guidelines help to focus decisions. Clinical decisions must also take into account patients’ personal values and preferences and their individual circumstances.

1.6.1 Level of evidence and grade of guideline recommendations

References used in the text have been assessed according to their level of scientific evidence (Table 1). Guideline recommendations have been graded (Table 2) in accordance with the Oxford Centre for Evidence-Based Medicine levels of evidence (LE) (16). The aim of grading recommendations (GR) is to provide transparency between the underlying evidence and the recommendation given.

Table 1: Level of evidence*

</tbody>
</table>

*Modified from Sackett et al. (16).

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of randomised controlled trials (RCTs) may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results.

Conversely, an absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences and cost when a grade is assigned (17-19).

The EAU Guidelines Office, do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the expert panels will include the information.

1.6.2 Publication history

A first version of the guidelines on the management of UTI and male genital infections was published in the EAU guidelines 2001 and in European Urology (20). A second updated version was included in the EAU guidelines 2006. The EAU/ICUD textbook on Urogenital Infections (21) has become the book of reference for the Guidelines and the recent update 2011. Guidelines on special conditions of the urogenital tract have also been published elsewhere (22-24).
Standard procedure for EAU publications includes an annual assessment of newly published literature in this field, guiding future updates. An ultra-short reference document is being published alongside this publication. All documents are available with free access through the EAU website Uroweb (http://www.uroweb.org/guidelines/online-guidelines/).

1.7 References

2. CLASSIFICATION OF UTIs

2.1 Introduction

Traditionally, UTIs are classified based on clinical symptoms, laboratory data, and microbiological findings. Practically, UTIs have been divided in uncomplicated and complicated UTIs, and sepsis. It is important to underline that the following proposed classification is still not validated or recognised. It is a working instrument useful for daily assessment and eventually for clinical research.

A critical review of present classifications was undertaken for the EAU/ICUD Urogenital Infections initiative (1) in Appendix 16.1. The overall aim is to provide the clinician and researcher with a standardised tool and nomenclature for UTI. The present guidelines give a short summary of a tentative improved system of classification of UTI based on:

- anatomical level of infection;
- grade of severity of infection;
- underlying risk factors;
- microbiological findings.

The symptoms, signs and laboratory finding focus on the anatomical level and the degree of severity of the infection. The risk factor analysis contributes to define any additional therapeutic measure required (i.e. drainage).

2.2 Anatomical level of infection

The symptoms, as presented in the Appendix 16.1, focus on the anatomical level of infection, defined as:

- urethra: urethritis (UR);
- urinary bladder: cystitis (CY);
- kidney: pyelonephritis (PN);
- blood stream: sepsis (US).
Figure 2.1 illustrates the basic diagnostic and treatment strategy for UTI. Urethritis, being poorly understood, is for the time being not included. Also the male accessory gland or genital infections (MAGI) orchitis, epididymitis and prostatitis are not included.

Asymptomatic bacteriuria (ABU) needs to be considered a special entity because it can have its source in both the lower and upper urinary tracts, and requires no treatment unless the patient is subjected to urological surgery.

2.3 Grade of severity
The grade of severity is set on a scale of 1-6 that is related to the risk of fatal outcome (Figure 2.1).

RF = Risk Factor; * = not well defined; ** = usually in combination with other RF (i.e. pregnancy, urological intervention).

2.4 Pathogens
Urine culture will usually identify the causative pathogen (> 10^4 cfu/mL) and its susceptibility pattern. Both characteristics can be introduced in the final classification of the clinical stage of infection. The degree of susceptibility is defined as grade a (susceptible) to c (resistant).

2.5 Classification of UTI
Figure 2.2 shows a summary of the additive parameters that make up an individual class of UTI.
By cumulating the different parameters, a UTI can be classified as follows (1):

- **CY-1R**: *E. coli* (a): simple cystitis but recurrent with susceptibility to standard antibiotics.
- **PN-3U**: *K pneumoniae* (b): severe pyelonephritis (with high fever and vomiting), with underlying urological disease (e.g. stones or obstruction) due to *Klebsiella* sp., with a moderate antibiotic resistance profile.
- **US-5C**: *Enterococcus* sp. (a): severe urosepsis with an antibiotic-sensitive *Enterococcus* sp. in a patient with an indwelling catheter.

### Reference

### 3. UNCOMPLICATED UTIs IN ADULTS

#### 3.1 Summary and recommendations
This chapter is by itself the summary of the EAU/ICUD initiative on urogenital infections, Chapter 3 on uncomplicated UTI (1).

#### 3.2 Definition
Acute, uncomplicated UTIs in adults include episodes of acute cystitis and acute pyelonephritis in otherwise healthy individuals. These UTIs are seen mostly in women without structural and functional abnormalities within the urinary tract, kidney diseases, or comorbidity that could lead to more serious outcomes and therefore require additional attention (2).

##### 3.2.1 Aetiological spectrum
The spectrum of aetiological agents is similar in uncomplicated upper and lower UTIs, with *E. coli* the causative pathogen in 70-95% of cases and *Staphylococcus saprophyticus* in 5-10%. Occasionally, other Enterobacteriaceae, such as *Proteus mirabilis* and *Klebsiella* sp., are isolated (3) (LE: 2a).

#### 3.3 Acute uncomplicated cystitis in premenopausal, non-pregnant women

##### 3.3.1 Diagnosis

1. **Clinical diagnosis**
   The diagnosis of acute uncomplicated cystitis can be made with a high probability based on a focused history of urinary irritative symptomatology (dysuria, frequency and urgency) and the absence of vaginal discharge or irritation, in those women who have no other risk factors for complicated UTIs (4) (LE: 2a, GR: B).

2. **Laboratory diagnosis**
   Urine dipstick testing, as opposed to urinary microscopy, is a reasonable alternative to urinalysis for diagnosis of acute uncomplicated cystitis (5,6) (LE: 2a, GR: B).

   Urine cultures are recommended for those with: (i) suspected acute pyelonephritis; (ii) symptoms that do not resolve or recur within 2-4 weeks after the completion of treatment; and (iii) those women who present with atypical symptoms (7,8) (LE: 4, GR: B).

   A colony count of $\geq 10^3$ cfu/mL of uropathogens is microbiologically diagnostic in women who present with symptoms of acute uncomplicated cystitis (9) (LE: 3, GR: B).

   Women who present with atypical symptoms of either acute uncomplicated cystitis or acute uncomplicated pyelonephritis, as well as those who fail to respond to appropriate antimicrobial therapy should be considered for additional diagnostic studies (LE: 4, GR: B).

##### 3.3.2 Therapy
Antibiotic therapy is recommended because clinical success is significantly more likely in women treated with antibiotics compared with placebo (10) (LE: 1a, GR: A).

The choice of an antibiotic for therapy should be guided by:
- spectrum and susceptibility patterns of the aetiologial uropathogens;
- efficacy for the particular indication in clinical studies;
- tolerability;
• adverse effects;
• cost;
• availability.

According to these principles and the available susceptibility patterns in Europe, fosfomycin trometamol 3 g single dose, pivmecillinam 400 mg for 3 days, and nitrofurantoin macrocrystal 100 mg bid for 5 days, are considered as drugs of first choice in many countries, when available (11-13) (LE: 1a, GR: A).

Cotrimoxazole 160/800 mg bid for 3 days or trimethoprim 200 mg for 5 days should only be considered as drugs of first choice in areas with known resistance rates for \(E. coli\) of < 20% (14,15) (LE: 1b, GR: B).

Alternative antibiotics are ciprofloxacin 250 mg bid, ciprofloxacin extended release 500 mg qd, levofloxacin 250 mg qd, norfloxacin 400 mg bid, and ofloxacin 200 mg bid, each as a 3-day course (16) (LE: 1b, GR: B). However, adverse effects have to be considered (Table 3.1).

\(^*\)not available in all countries.
\(^*\)available only in Scandinavia, the Netherlands, Austria, and Canada.

3.3.3 Follow-up
Routine post-treatment urinalysis or urine cultures in asymptomatic patients are not indicated (17) (LE: 2b, GR: B). In women whose symptoms do not resolve by the end of treatment, and in those whose symptoms resolve but recur within 2 weeks, urine culture and antimicrobial susceptibility tests should be performed (LE: 4, GR: B). For therapy in this situation, one should assume that the infecting organism is not susceptible to the agent originally used. Retreatment with a 7-day regimen using another agent should be considered (LE: 4, GR: C).

3.4 Acute uncomplicated pyelonephritis in premenopausal, non-pregnant women

3.4.1 Diagnosis
3.4.1.1 Clinical diagnosis
Acute pyelonephritis is suggested by flank pain, nausea and vomiting, fever (> 38°C), or costovertebral angle tenderness, and it can occur in the absence of symptoms of cystitis (18).

3.4.1.2 Laboratory diagnosis
Urinalysis (e.g. using a dipstick method), including the assessment of white and red blood cells and nitrites, is recommended for routine diagnosis (19) (LE: 4, GR: C).

Colony counts \(\geq 10^6\) cfu/mL of uropathogens are considered to be indicative of clinically relevant bacteriuria (20) (LE: 2b, GR: C).
### 3.4.1.3 Imaging diagnosis

Evaluation of the upper urinary tract with ultrasound should be performed to rule out urinary obstruction or renal stone disease (LE: 4, GR: C).

Additional investigations, such as an unenhanced helical computed tomography (CT), excretory urography, or dimercaptosuccinic acid (DMSA) scanning, should be considered if the patients remain febrile after 72 h of treatment (LE: 4, GR: C).

### 3.4.2 Therapy

As a result of the lack of suitable surveillance studies, the spectrum and susceptibility patterns of uropathogens that cause uncomplicated cystitis can be used as a guide for empirical therapy (3) (LE: 4, GR: B). However, *S. saprophyticus* is less frequent in acute pyelonephritis as compared to acute cystitis (LE: 4, GR: B).

#### 3.4.2.1 Mild and moderate cases of acute uncomplicated pyelonephritis (Table 3.2)

In mild and moderate cases of acute uncomplicated pyelonephritis, oral therapy of 10-14 days is usually sufficient (LE: 1b, GR: B). A fluoroquinolone for 7-10 days can be recommended as first-line therapy if the resistance rate of *E. coli* is still < 10% (21) (LE: 1b, GR: A). If the fluoroquinolone dose is increased, the treatment can probably be reduced to 5 days (22,23) (LE: 1b, GR: B). However, increasing numbers of fluoroquinolone-resistant *E. coli* in the community have already been found in some parts of the world, thus restricting the empirical use of fluoroquinolones.

A third-generation oral cephalosporin, such as cefpodoxime proxetil or ceftibuten, could be an alternative (24,25) (LE: 1b, GR: B). However, available studies have demonstrated only equivalent clinical, but not microbiological, efficacy compared with ciprofloxacin.

As a result of increasing *E. coli* resistance rates >10%, cotrimoxazole is not suitable for empirical therapy in most areas, but it can be used after sensitivity has been confirmed through susceptibility testing (26) (LE: 1b, GR: B).

Co-amoxiclav is not recommended as a drug of first choice for empirical oral therapy of acute pyelonephritis (LE: 4, GR: B). It is recommended when susceptibility testing shows a susceptible Gram-positive organism (LE: 4, GR: C).

In communities with high rates of fluoroquinolone-resistant and extended-spectrum β-lactamase (ESBL)-producing *E. coli* (> 10%), initial empirical therapy with an aminoglycoside or carbapenem has to be considered until susceptibility testing demonstrates that oral drugs can also be used (LE: 4, GR: B).

#### 3.4.2.2 Severe cases of acute uncomplicated pyelonephritis (Table 3.2)

Patients with severe pyelonephritis who cannot take oral medication because of systemic symptoms such as nausea and vomiting, have to be treated initially with one of the following parenteral antibiotics:

<table>
<thead>
<tr>
<th>LE</th>
<th>GR</th>
</tr>
</thead>
<tbody>
<tr>
<td>A parenteral fluoroquinolone, in communities with <em>E. coli</em> fluoroquinolone-resistance rates &lt; 10%.</td>
<td>1b</td>
</tr>
<tr>
<td>A third-generation cephalosporin, in communities with ESBL-producing <em>E. coli</em> resistance rates &lt; 10%.</td>
<td>1b</td>
</tr>
<tr>
<td>An aminopenicillin plus a β-lactamase-inhibitor in cases of known susceptible Gram-positive pathogens.</td>
<td>4</td>
</tr>
<tr>
<td>An aminoglycoside or carbapenem in communities with fluoroquinolone and/or ESBL-producing <em>E. coli</em> resistance rates &gt; 10%.</td>
<td>1b</td>
</tr>
</tbody>
</table>

Hospital admission should be considered if complicating factors cannot be ruled out by available diagnostic procedures and/or the patient has clinical signs and symptoms of sepsis (LE: 4, GR: B).

After improvement, the patient can be switched to an oral regimen using one of the above-mentioned antibacterials, if active against the infecting organism, to complete the 1-2-week course of therapy (LE: 1b, GR: B).
Table 3.2: Recommended initial empirical antimicrobial therapy in acute uncomplicated pyelonephritis in otherwise healthy premenopausal women

</tr>
</tbody>
</table>

Alternatives (clinical but not microbiological equivalent efficacy compared with fluoroquinolones):

- Cefpodoxime proxetil 200 mg bid 10 days (25)
- Cefditoren 400 mg qd 10 days (24)

Only if the pathogen is known to be susceptible (not for initial empirical therapy):

- Trimethoprim-sulphamethoxazole 160/800 mg bid 14 days (21)
- Co-amoxiclav²,³ 0.5/0.125 g tid 14 days

¹lower dose studied, but higher dose recommended by experts.
²not studied as monotherapy for acute uncomplicated pyelonephritis.
³mainly for Gram-positive pathogens.

II. Initial parenteral therapy in severe cases

After improvement, the patient can be switched to an oral regimen using one of the above-mentioned antibacterials (if active against the infecting organism) to complete the 1-2-week course of therapy. Therefore, only daily dose and no duration of therapy are indicated.

  - urological investigation for complicating factors drainage, in case of obstruction or abscess
  - total duration of therapy 2-3 Weeks

*BLI = β-lactamase inhibitor; TMP = trimethoprim; SMX = sulphamethoxazole.*
3.4.3 **Follow-up**

Routine post-treatment urinalysis and urine cultures in an asymptomatic patient might not be indicated (LE: 4, GR: C).

In women whose pyelonephritis symptoms do not improve within 3 days, or resolve and then recur within 2 weeks, repeated urine culture and antimicrobial susceptibility tests and an appropriate investigation, such as renal ultrasound, CT or renal scintigraphy, should be performed (LE: 4, GR: B).

In patients with no urological abnormality, it should be assumed that the infecting organism is not susceptible to the agent originally used, and an alternative tailored treatment should be considered based on culture results (LE: 4, GR: B).

For patients who relapse with the same pathogen, the diagnosis of uncomplicated pyelonephritis should be reconsidered. Appropriate diagnostic steps are necessary to rule out any complicating factors (LE: 4, GR: C).

An algorithm of the clinical management of acute pyelonephritis is shown in Figure 3.1.

3.5 **Recurrent (uncomplicated) UTIs in women**

3.5.1 **Diagnosis**

Recurrent UTIs are common among young, healthy women, even though they generally have anatomically and physiologically normal urinary tracts (33) (LE: 2a).

Recurrent UTIs need to be diagnosed by urine culture (LE: 4, GR: A). Excretory urography, cystography and cystoscopy are not routinely recommended for evaluation of women with recurrent UTIs (34) (LE: 1b, GR: B).

3.5.2 **Prevention**

Different therapeutic options can be recommended to the patient.

3.5.2.1 **Antimicrobial prophylaxis**

Antimicrobial prophylaxis for prevention of recurrent UTI should be considered only after counselling and behavioural modification has been attempted (LE: 4, GR: A).

Before any prophylaxis regimen is initiated, eradication of a previous UTI should be confirmed by a negative urine culture 1-2 weeks after treatment (LE: 4, GR: A).

Continuous or postcoital antimicrobial prophylaxis should be considered to prevent recurrent uncomplicated cystitis in women in whom non-antimicrobial measures have been unsuccessful (35) (LE: 1a, GR: A). The choice of antibiotics should be based upon the identification and susceptibility pattern of the organism that causes the UTI and the patient's history of drug allergies. Drug regimens are shown in Tables 3.3 and 3.4.

**Table 3.3: Continuous antimicrobial prophylaxis regimens for women with recurrent UTIs (33)**

*Trimethoprim-sulfamethoxazole

In appropriate women with recurrent uncomplicated cystitis, self-diagnosis and self-treatment with a short-course regimen of an antimicrobial agent should be considered (36) (LE: 2b, GR: A).

3.5.2.2  Immunoactive prophylaxis
OM-89 (Uro-Vaxom®) is sufficiently well-documented and has been shown to be more effective than placebo in several randomised trials. Therefore, it can be recommended for immunoprophylaxis in female patients with recurrent uncomplicated UTI (37,38) (LE: 1a, GR: B). Its efficacy in other groups of patients, and its efficacy relative to antimicrobial prophylaxis remain to be established.

For other immunotherapeutic products on the market, larger phase III studies are still missing. In smaller phase II studies, StroVac® and Solco-Urovac® have been shown to be effective when administered with a booster cycle of the same agents (LE: 1a, GR: C).

For other immunotherapeutic products, such as Urostim® and Urvakol®, no controlled studies are available. Therefore, no recommendations are possible.

3.5.2.3  Prophylaxis with probiotics
Accessibility of clinically proven probiotics for UTI prophylaxis is currently not universal. Only the Lactobacillus strains specifically tested in studies should be used for prophylaxis.

When commercially available, it is reasonable to consider the use of intravaginal probiotics that contain L. rhamnosus GR-1 and L. reuteri RC-14 for the prevention of recurrent UTI (39), and these products can be used once or twice weekly (LE: 4, GR: C).

Daily use of the oral product with strains GR-1 and RC-14 is worth testing given that it can restore the vaginal lactobacilli, compete with urogenital pathogens, and prevent bacterial vaginosis, a condition that increases the risk of UTI (39) (LE: 1b, GR: C).

3.5.2.4  Prophylaxis with cranberry
Despite the lack of pharmacological data and the small number of weak clinical studies, there is evidence to suggest that cranberry (Vaccinium macrocarpon) is useful in reducing the rate of lower UTIs in women (40,41) (LE: 1b, GR: C).

For everyday practice, the daily consumption of cranberry products, giving a minimum of 36 mg/day proanthocyanidin A (the active compound), is recommended (LE: 1b, GR: C). The best approach is to use those compounds that have demonstrated clear bioactivity in urine.

3.6  UTIs in pregnancy
Urinary tract infections and asymptomatic bacteriuria are common during pregnancy. Most women are prone to or acquire asymptomatic bacteriuria before pregnancy, and 20-40% of women with asymptomatic bacteriuria develop pyelonephritis during pregnancy.

3.6.1  Diagnosis of UTI in pregnant women
Diagnostic criteria of acute cystitis and pyelonephritis in otherwise healthy pregnant women are similar to that of non-pregnant women (3.3.1 and 3.4.1). However, physical examination and urinalysis including urine culture are highly recommended in cystitis. In addition, in case of suspicion of pyelonephritis, ultrasound of the kidneys and urinary tract is necessary.

3.6.2  Definition of bacteriuria
- In a pregnant woman, asymptomatic bacteriuria is diagnosed in case of two consecutive voided urine
specimens with growth of $\geq 10^5$ cfu/mL of the same bacterial species; or a single catheterised specimen with growth of $\geq 10^5$ cfu/mL of a uropathogen (LE: 2a, GR: A).

- In a pregnant woman with symptoms compatible with UTI, bacteriuria is considered relevant if a voided or catheterised urine specimen grows $\geq 10^3$ cfu/mL of a uropathogen (LE: 4, GR: B).

3.6.3 Screening
Pregnant women should be screened for bacteriuria during the first trimester (LE: 1a, GR: A).

3.6.4 Treatment of asymptomatic bacteriuria and acute cystitis
Asymptomatic bacteriuria detected during pregnancy should be eradicated with antimicrobial therapy (LE: 1a, GR: A). Acute cystitis should be adequately treated. Recommended antibiotic regimens are listed in Table 3.5.

Table 3.5: Treatment regimens for asymptomatic bacteriuria and cystitis in pregnancy (44)

G6PD = glucose-6-phosphate dehydrogenase

3.6.5 Duration of therapy
Short courses of antimicrobial therapy (3 days) should be considered for the treatment of asymptomatic bacteriuria and cystitis in pregnancy (LE: 1a, GR: A).

3.6.6 Follow-up
Urine cultures should be obtained 1-2 weeks after completion of therapy for asymptomatic bacteriuria and symptomatic UTI in pregnancy (LE: 4, GR: A).

3.6.7 Prophylaxis
Postcoital prophylaxis should be considered in pregnant women with a history of frequent UTIs before onset of pregnancy, to reduce their risk of UTI (LE: 2b, GR: B).

3.6.8 Treatment of pyelonephritis
Outpatient management with appropriate antibiotics should be considered in women with pyelonephritis in pregnancy, provided symptoms are mild and close follow-up is feasible (LE: 1b, GR: A). Recommended parenteral antibiotic regimens are shown in Table 3.6 (45,46). After clinical improvement parenteral therapy can be switched to oral therapy for a total treatment duration of 7-10 days (LE: 4; GR:B).

3.6.9 Complicated UTI
For diagnostics of complicating factors within the urinary tract, ultrasonography or magnetic resonance imaging (MRI) should be used preferentially to avoid radiation risk to the foetus (LE: 4; GR: B). Treatment
follows the same general principles as outlines in 4.4. Appropriate antimicrobial therapy for 7-10 days and the management of any urological abnormality are mandatory. Hospitalisation is usually required and supportive care as required.

### 3.7 UTIs in postmenopausal women

#### 3.7.1 Risk factors

<table>
<thead>
<tr>
<th>Reference</th>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>47</td>
<td>2a</td>
</tr>
</tbody>
</table>

In older institutionalised women, urine catheterisation and functional status deterioration appear to be the most important risk factors associated with UTI.

Atrophic vaginitis.

Incontinence, cystocele and post-voiding residual urine.

UTI before menopause.

Non-secretor status of blood group antigens.

#### 3.7.2 Diagnosis

Diagnosis of UTI in postmenopausal women should always consider the following:

<table>
<thead>
<tr>
<th>Reference</th>
<th>LE</th>
<th>GR</th>
</tr>
</thead>
<tbody>
<tr>
<td>4</td>
<td>B</td>
<td></td>
</tr>
<tr>
<td>48</td>
<td>1b</td>
<td>B</td>
</tr>
</tbody>
</table>

#### 3.7.3 Treatment

<table>
<thead>
<tr>
<th>Reference</th>
<th>LE</th>
<th>GR</th>
</tr>
</thead>
<tbody>
<tr>
<td>49</td>
<td>1b</td>
<td>C</td>
</tr>
</tbody>
</table>

Treatment of acute cystitis in postmenopausal women is similar to that in premenopausal women, however, short-term therapy is not so well-established as in premenopausal women.

Treatment of pyelonephritis in postmenopausal women is similar to that in premenopausal women.

Asymptomatic bacteriuria in elderly women should not be treated with antibiotics.

Optimal antimicrobials, doses and duration of treatment in elderly women appear to be similar to those recommended for younger postmenopausal women.

Oestrogen (especially vaginal) can be administered for prevention of UTI, but results are contradictory.

Alternative methods, such as cranberry and probiotic lactobacilli, can contribute but they are not sufficient to prevent recurrent UTI.

If complicating factors, such as urinary obstruction and neurogenic bladder, are ruled out, antimicrobial prophylaxis should be carried out as recommended for premenopausal women.

### 3.8 Acute uncomplicated UTIs in young men

#### 3.8.1 Men with acute uncomplicated UTI

4. COMPLICATED UTIs DUE TO UROLOGICAL DISORDERS

4.1 Summary and recommendations
A complicated UTI is an infection associated with a condition, such as a structural or functional abnormality of the genitourinary tract, or the presence of an underlying disease that interferes with host defence mechanisms, which increase the risks of acquiring infection or of failing therapy. Examples of risk factors are listed in Table 2.1.

A broad range of bacteria can cause a complicated UTI. The spectrum is much larger than in uncomplicated UTIs, and bacteria are more likely to be resistant to antimicrobials, especially in a treatment-related complicated UTI.

Enterobacteriaceae are the predominant pathogens, with *E. coli* being the most common pathogen. However, non-fermenters (e.g. *Pseudomonas aeruginosa*) and Gram-positive cocci (e.g. staphylococci and enterococci) may also play an important role, depending on the underlying conditions.

Treatment strategy depends on the severity of the illness. Treatment encompasses three goals: management of the urological abnormality, antimicrobial therapy, and supportive care when needed. Hospitalisation is often required. To avoid the emergence of resistant strains, therapy should be guided by urine culture whenever possible.

If empirical therapy is necessary, the antibacterial spectrum of the antibiotic agent should include the most relevant pathogens (GR: A). A fluoroquinolone with mainly renal excretion, an aminopenicillin plus a β-lactamase inhibitor (BLI), a Group 2 or 3a cephalosporin or, in the case of parenteral therapy, an aminoglycoside, are recommended alternatives (LE: 1b, GR: B).

In case of failure of initial therapy, or in case of clinically severe infection, a broader-spectrum antibiotic should be chosen that is also active against *Pseudomonas* (LE: 1b, GR: B), e.g. a fluoroquinolone (if not used for initial therapy), an acylaminopenicillin (piperacillin) plus a BLI, a Group 3b cephalosporin, or a carbapenem, with or without combination with an aminoglycoside (LE: 1b, GR: B).

The duration of therapy is usually 7-14 days (LE: 1b, GR: A), but sometimes has to be prolonged for up to 21 days (LE: 1b, GR: A).

Until predisposing factors are completely removed, true cure without recurrent infection is usually not possible. Therefore, a urine culture should be carried out 5-9 days after completion of therapy and also 4-6 weeks later (GR: B).

4.2 Definitions and classification
A complicated UTI is an infection associated with a condition, such as structural or functional abnormalities
of the genitourinary tract or the presence of an underlying disease, which increases the risks of acquiring an infection or of failing therapy (1-3). Two criteria are mandatory to define a complicated UTI: a positive urine culture and one or more of the factors listed in Table 4.1.

Table 4.1: Factors that suggest a potential complicated UTI

</tr>
</tbody>
</table>

Complicated UTI can arise in a heterogeneous group of patients. However, neither patient age nor sex per se are part of the definition of a complicated UTI. With regard to prognosis and clinical studies, it is advisable to stratify complicated UTIs due to urological disorders into at least two groups (4):

1. Patients in whom the complicating factors could be eliminated by therapy, e.g. stone extraction, removal of an indwelling catheter.
2. Patients in whom the complicating factor could not be or is not removed satisfactorily during therapy, e.g. permanent indwelling catheter, stone residues after treatment or neurogenic bladder.

4.2.1 **Clinical presentation**

A complicated UTI may or may not be associated with clinical symptoms (e.g. dysuria, urgency, frequency, flank pain, costovertebral angle tenderness, suprapubic pain and fever). Clinical presentation can vary from severe obstructive acute pyelonephritis with imminent urosepsis to a catheter-associated postoperative UTI, which might disappear spontaneously as soon as the catheter is removed. It also has to be recognised that symptoms, especially lower urinary tract symptoms (LUTS), are not only caused by UTIs but also by other urological disorders, such as benign prostatic hyperplasia (BPH) or transurethral resection of the prostate (TURP).

Apart from urological abnormalities, concomitant medical conditions, such as diabetes mellitus (10%) and renal failure, which can be related to urological abnormalities (5), are often present in a complicated UTI. These are discussed in more details in Sections 8.1.3 and 8.1.4 on UTIs in renal insufficiency, transplant recipients, diabetes mellitus and immunosuppression.

4.2.2 **Urine cultures**

Significant bacteriuria in a complicated UTI is defined by counts of \( \geq 10^5 \) cfu/mL and \( \geq 10^4 \) cfu/mL, in the midstream urine (MSU) of women and men, respectively (1,2). If a straight catheter urine sample is taken, \( \geq 10^4 \) cfu/mL can be considered relevant. For an asymptomatic patient, two consecutive urine cultures (at least 24 h apart) yielding \( \geq 10^6 \) cfu/mL of the same microorganism are required. The requirement for pyuria is \( \geq 10 \) white blood cells (WBC) per high-power field (x400) in the resuspended sediment of a centrifuged aliquot of urine or per mm\(^3\) in unspun urine. A dipstick method can also be used for routine assessment, including a leukocyte esterase test, haemoglobin and probably a nitrite reaction.

4.3 **Microbiology**

4.3.1 **Spectrum and antibiotic resistance**

Patients with a complicated UTI, both community and hospital-acquired, tend to show a diversity of microorganisms with a higher prevalence of resistance against antimicrobials, and higher rates of treatment failure if the underlying abnormality cannot be corrected.

However, the presence of a resistant strain on its own is not enough to define a complicated UTI. Urinary abnormality (anatomical or functional) or the presence of an underlying disease predisposing to a UTI is also necessary.

A broad range of bacteria can cause a complicated UTI. The spectrum is much larger than with an uncomplicated UTI and the bacteria are more likely to be antibiotic-resistant (especially in a treatment-related complicated UTI) than those isolated in an uncomplicated UTI. *E. coli, Proteus, Klebsiella, Pseudomonas and*
4.3.2 Complicated UTIs associated with urinary stones
In the subset of complicated UTIs related to urinary stones, the frequency of *E. coli* and enterococci infection seems less important pathogens. In contrast, a greater portion of *Proteus* and *Pseudomonas* sp. (9) is found. Of the urease-producing organisms, *Proteus, Providencia* and *Morganella* sp., and *Corynebacterium urealyticum* are predominant, but *Klebsiella, Pseudomonas* and *Serratia* sp. and staphylococci are also urease producers to a certain extent.

Among patients with staghorn calculus disease, 88% were found to have a UTI at the time of diagnosis, with 82% of patients infected with urease-producing organisms (10). The enzyme, urease, splits urea into carbon dioxide and ammonia. The resultant increase in ammonia in the urine injures the glycosaminoglycan layer, which in turn increases bacterial adherence (11) and enhances the formation of struvite crystals. These aggregate to form renal stones and incrustations on urinary catheters (12).

The pathogenic potential of coagulase-negative staphylococci and non-group D streptococci is controversial (13,14). Under certain circumstances, such as the presence of a stone or foreign bodies, staphylococci can be relevant pathogens. Otherwise, staphylococci are not so common in complicated UTIs (0-11%), according to published reports (6,15).

4.3.3 Complicated UTIs associated with urinary catheters
In catheter-associated UTIs, the distribution of microorganisms is similar (16), and biofilm has to be considered. Antimicrobial therapy may only be effective in the early stages of the infection (15). For more details see Chapter 6 on catheter-associated UTIs.

4.4 Treatment

4.4.1 General principles
Treatment strategy depends on the severity of the illness. Appropriate antimicrobial therapy and the management of the urological abnormality are mandatory. If needed, supportive care is given. Hospitalisation is often necessary depending on the severity of the illness.

4.4.2 Choice of antibiotics
Empirical treatment of a symptomatic complicated UTI requires a knowledge of the spectrum of possible pathogens and local antibiotic resistance patterns, as well as assessment of the severity of the underlying urological abnormality (including the evaluation of renal function).

Bacteraemia is usually reported too late to influence the choice of antibiotics. However, suspicion of bacteraemia must influence the empirical treatment. The severity of the associated illness and the underlying urological condition are still of the utmost importance for prognosis.

Many therapeutic trials have been published on the use of specific antimicrobial therapies in complicated UTIs. Unfortunately, most reports are of limited use for the practical management of the patient in a day-to-day situation because of limitations such as:

- poor characterisation of the patient populations;
- unclear evaluation of the severity of the illness;
- nosocomial and community-acquired infections are not accurately distinguished;
- urological outcome is seldom taken into consideration.

Intense use of any antimicrobial, especially when used on an empirical basis in this group of patients with a high likelihood of recurrent infection, will lead to the emergence of resistant microorganisms in subsequent infections. Whenever possible, empirical therapy should be replaced by a therapy adjusted for the specific infective organisms identified in the urine culture. Therefore, a urine specimen for culture must be obtained before initiation of therapy, and the selection of an antimicrobial agent should be re-evaluated once culture results are available (7). To date, it has not been shown that any agent or class of agents is superior in cases in which the infective organism is susceptible to the drug administered.

In patients with renal failure, whether related to a urological abnormality or not, appropriate dose adjustments have to be made.

If empirical treatment is necessary, fluoroquinolones with mainly renal excretion are recommended because they have a large spectrum of antimicrobial activity that covers most of the expected pathogens, and they reach high concentration levels both in the urine and the urogenital tissues. Fluoroquinolones can be used orally as well as parenterally. An aminopenicillin plus a BLI, a Group 2 or 3a cephalosporin, or, in the case of parenteral therapy, an aminoglycoside, are alternatives. A new Group 1 oral carbapenem, ertapenem, in a
prospective randomised trial, has been shown to be as effective as ceftriaxone (16).

In most countries, \textit{E. coli} shows a high rate of resistance against TMP-SMX (18-25% in the latest evaluation in the USA) (17) and should therefore be avoided as a first-line treatment. Fosfomycin trometamol is licensed only for a single-dose therapy of uncomplicated cystitis (18). The aminopenicillins, ampicillin or amoxicillin, are no longer sufficiently active against \textit{E. coli}.

In the case of failure of initial therapy, or if microbiological results are not yet available, or as initial therapy in the case of clinically severe infection, treatment should be switched to an antibiotic with a broader spectrum that is also active against \textit{Pseudomonas}, such as a fluoroquinolone (if not used for initial therapy), an acylaminopenicillin (piperacillin) plus a BLI, a Group 3b cephalosporin, or a carbapenem, eventually in combination with an aminoglycoside. Similarly, many experts concur that empirical therapy for the institutionalised or hospitalised patients with a serious UTI should include an intravenous antipseudomonal agent because of an increased risk of urosepsis (19).

Patients can generally be treated as outpatients. In more severe cases (e.g. hospitalised patients), antibiotics have to be given parenterally. A combination of an aminoglycoside with a BLI or a fluoroquinolone is widely used for empirical therapy. After a few days of parenteral therapy and clinical improvement, patients can be switched to oral treatment. Therapy has to be reconsidered when the infective strains have been identified and their susceptibilities are known.

The successful treatment of a complicated UTI always combines effective antimicrobial therapy, optimal management of the underlying urological abnormalities or other diseases, and sufficient life-supporting measures. The antibacterial treatment options are summarised in Table 4.2 and Appendix 16.2 (Recommendations for antimicrobial therapy in urology).

4.4.3 \textbf{Duration of antibiotic therapy}

Treatment for 7-14 days is generally recommended, but the duration should be closely related to the treatment of the underlying abnormality (1). Sometimes, a prolongation for up to 21 days, according to the clinical situation, is necessary (2).

4.4.4 \textbf{Complicated UTIs associated with urinary stones}

If a nidus of a stone or an infection remains, stone growth will occur. Complete removal of the stones and adequate antimicrobial therapy are both needed. Eradication of the infection will probably eliminate the growth of struvite calculi (20). Long-term antimicrobial therapy should be considered if complete removal of the stone cannot be achieved (21).

4.4.5 \textbf{Complicated UTIs associated with indwelling catheters}

Current data do not support the treatment of asymptomatic bacteriuria, either during short-term catheterisation (< 30 days) or during long-term catheterisation, because it will promote the emergence of resistant strains (22,23). In short-term catheterisation, antibiotics may delay the onset of bacteriuria, but do not reduce complications (24).

A symptomatic complicated UTI associated with an indwelling catheter is treated with an agent with as narrow a spectrum as possible, based on culture and sensitivity results. The optimal duration is not well established. Treatment durations that are too short as well as too long may cause the emergence of resistant strains. A 7-day course could be a reasonable compromise.

4.4.6 \textbf{Complicated UTIs in patients with spinal cord injury}

In case of persistent UTIs and suspicion of urinary retention, a full urodynamic assessment to appraise bladder function is to be carried out. Priority is to ensure proper drainage of the bladder to protect the urinary tract. For further details, see the EAU guidelines on Neurogenic Lower Urinary Tract Dysfunction (25).

It is generally accepted that asymptomatic bacteriuria in patients with spinal cord injury should not be treated (26), even in cases of intermittent catheterisation. For symptomatic episodes of infection in patients with spinal cord injury, only a few studies have investigated the most appropriate agent and duration of therapy. Currently, 7-10 days of therapy is most commonly used. There is no superiority of one agent or class of antimicrobials in this group of patients.

Antimicrobial treatment options are summarised in Table 4.2.

BLI = β-lactam inhibitor

4.4.7 Follow-up after treatment
The greater likelihood of the involvement of resistant microorganisms in complicated UTIs is another feature of these infectious diseases. This is not a priori related to the urinary abnormality, but is related more to the fact that patients with a complicated UTI tend to have recurrent infection. For these reasons, before and after the completion of the antimicrobial treatment, urine cultures must be obtained for the identification of the microorganisms and the evaluation of susceptibility testing.

5. SEPSIS SYNDROME IN UROLOGY (UROSEPSIS)

5.1 Summary and recommendations
Patients with urosepsis should be diagnosed at an early stage, especially in the case of a complicated UTI. The systemic inflammatory response syndrome, known as SIRS (fever or hypothermia, hyperleukocytosis or leukopenia, tachycardia, tachypnoea), is recognised as the first event in a cascade to multi-organ failure. Mortality is considerably increased when severe sepsis or septic shock are present, although the prognosis of urosepsis is globally better than that of sepsis from other infectious sites.

The treatment of urosepsis calls for the combination of adequate life-supporting care, appropriate and prompt antibiotic therapy, adjunctive measures (e.g. sympathomimetic amines, hydrocortisone, blood glucose control) and the optimal management of urinary tract disorders (LE: 1a, GR: A). The drainage of any obstruction in the urinary tract is essential as first-line treatment (LE: 1b, GR: A). Urologists are recommended to treat patients in collaboration with intensive care and infectious diseases specialists (LE: 2a, GR: B).

Urosepsis is seen in both community-acquired and healthcare associated infections. Most nosocomial urosepsis can be avoided by measures used to prevent nosocomial infection, e.g. reduction of hospital stay, early removal of indwelling urethral catheters, avoidance of unnecessary urethral catheterisation, correct use of closed catheter systems, and attention to simple daily asepsis techniques to avoid cross-infection (LE: 2a, GR: B).

5.2 Background
Urinary tract infections can manifest as bacteriuria with limited clinical symptoms, sepsis or severe sepsis, depending on localised or systemic extension. Sepsis is diagnosed when clinical evidence of infection is accompanied by signs of systemic inflammation (fever or hypothermia, tachycardia, tachypnoea, leukocyturia or leukopenia). Severe sepsis is defined by the presence of symptoms of organ dysfunction, and septic shock by the presence of persistent hypotension associated with tissue anoxia.

Severe sepsis is a severe situation with a reported mortality rate of 20-42% (1). Most severe sepsis reported in the literature is related to pulmonary (50%) or abdominal (24%) infections, with UTIs accounting for only 5% (2). Sepsis is more common in men than in women (3). In recent years, the incidence of sepsis has increased by 8.7% per year (1), but the associated mortality has decreased, which suggests improved management of patients (total in-hospital mortality rate fell from 27.8% to 17.9% during 1995-2000) (4). Globally (this is not true for urosepsis), the rate of sepsis due to fungal organisms has increased while Gram-positive bacteria have become the predominant pathogen in sepsis, even if Gram-negative bacteria remain predominant in urosepsis.

In urosepsis, as in other types of sepsis, the severity depends mostly upon the host response. Patients who are more likely to develop urosepsis include: elderly patients; diabetics; immunosuppressed patients, such as transplant recipients; patients receiving cancer chemotherapy or corticosteroids; and patients with AIDS. Urosepsis also depends on local factors, such as urinary tract calculi, obstruction at any level in the urinary tract, congenital uropathy, neurogenic bladder disorders, or endoscopic manoeuvres. However, all patients can be affected by bacterial species that are capable of inducing inflammation within the urinary tract. Moreover, it is now recognised that SIRS may be present without infection (e.g. pancreatitis, burns, or non-septic shock) (5).

For therapeutic purposes, the diagnostic criteria of sepsis should identify patients at an early stage of the syndrome, which should prompt urologists and intensive care specialists to search for and treat infection, apply appropriate therapy, and monitor for organ failure and other complications.

5.3 Definition and clinical manifestation of sepsis in urology
The clinical evidence of UTI is based on symptoms, physical examination, sonographic and radiological features, and laboratory data, such as bacteriuria and leukocyturia. The following definitions apply (Table 5.1):
- Sepsis is a systemic response to infection. The symptoms of SIRS which were initially considered to be “mandatory” for the diagnosis of sepsis (5), are now considered to be alerting symptoms (6). Many
other clinical or biological symptoms must be considered.  
- Severe sepsis is sepsis associated with organ dysfunction.  
- Septic shock is persistence of hypoperfusion or hypotension despite fluid resuscitation.  
- Refractory septic shock is defined by an absence of response to therapy.

Table 5.1: Clinical diagnostic criteria of sepsis and septic shock (5,6)

</tbody>
</table>
| Systemic inflammatory response syndrome (SIRS) | Response to a wide variety of clinical insults, which can be infectious, as in sepsis but may be non-infectious in aetiology (e.g. burns, or pancreatitis). This systemic response is manifested by two or more of the following conditions:  
  - Temperature > 38°C or < 36°C  
  - Heart rate > 90 bpm  
  - Respiratory rate > 20 breaths/min or PaCO2 < 32 mmHg (< 4.3 kPa)  
  - WBC > 12,000 cells/mm3 or < 4,000 cells/mm3 or > 10% immature (band) forms |
| Sepsis                           | Activation of the inflammatory process due to infection.                   |
| Hypotension                      | Systolic blood pressure < 90 mmHg or a reduction of > 40 mmHg from baseline in the absence of other causes of hypotension. |
| Severe sepsis                    | Sepsis associated with organ dysfunction, hypoperfusion or hypotension.    
  Hypoperfusion and perfusion abnormalities may include but are not limited to lactic acidosis, oliguria or acute alteration of mental status. |
| Septic shock                     | Sepsis with hypotension despite adequate fluid resuscitation along with the presence of perfusion abnormalities that may include, but are not limited to lactic acidosis, oliguria, or acute alteration in mental status. Patients who are on inotrope or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured. |
| Refractory septic shock          | Septic shock that lasts for > 1 h and does not respond to fluid administration or pharmacological intervention. |

5.4 Physiology and biochemical markers
Microorganisms reach the urinary tract by way of the ascending, haematogenous, or lymphatic routes. For urosepsis to be established, the pathogens have to reach the bloodstream. The risk of bacteraemia is increased in severe UTIs, such as pyelonephritis and acute bacterial prostatitis, and is facilitated by obstruction of the urinary tract. E. coli remains the most prevalent microorganism. In several countries, some bacterial strains can be resistant to quinolones or third-generation cephalosporins. Some microorganisms are multi-resistant, such as methicillin-resistant Staphylococcus aureus (MRSA), P. aeruginosa and Serratia sp. and therefore difficult to treat. Most commonly, the condition develops in compromised patients (e.g. those with diabetes or immunosuppression), with typical signs of generalised sepsis associated with local signs of infection. A fatal outcome is described in 20-40% of all patients.

5.4.1 Cytokines as markers of the septic response
Cytokines are involved in the pathogenesis of sepsis syndrome. They are peptides that regulate the amplitude and duration of the host inflammatory response. They are released from various cells including monocytes, macrophages and endothelial cells, in response to various infectious stimuli. When they become bound to specific receptors on other cells, cytokines change their behaviour in the inflammatory response. The complex balance between pro- and anti-inflammatory responses is modified in severe sepsis. An immunosuppressive phase follows the initial pro-inflammatory mechanism. Other cytokines are involved such as interleukins (ILs).
Tumour necrosis factor (TNF)-α, IL-1, IL-6 and IL-8 are cytokines that are associated with sepsis. Sepsis may indicate an immune system that is severely compromised and unable to eradicate pathogens or a non-regulated and excessive activation of inflammation, or both. Genetic predisposition is a probable explanation of sepsis in several patients. Mechanisms of organ failure and death in patients with sepsis remain only partially understood (2).

5.4.2 Procalcitonin is a potential marker of sepsis
Procalcitonin is the propeptide of calcitonin, but is devoid of hormonal activity. Normally, levels are undetectable in healthy humans. During severe generalised infections (bacterial, parasitic and fungal) with systemic manifestations, procalcitonin levels may rise to > 100 ng/mL. In contrast, during severe viral infections or inflammatory reactions of non-infectious origin, procalcitonin levels show only a moderate or no increase. The exact site of procalcitonin production during sepsis is not known. Procalcitonin monitoring may be useful in patients likely to develop a SIRS of infectious origin. High procalcitonin levels, or an abrupt increase in levels in these patients, should prompt a search for the source of infection. Procalcitonin may be useful in differentiating between infectious and non-infectious causes of severe inflammatory status (7,8).

5.5 Prevention
Septic shock is the most frequent cause of death for patients hospitalised for community-acquired and nosocomial infection (20-40%). Sepsis initiates the cascade that progresses to severe sepsis and then septic shock in a clinical continuum. Urosepsis treatment calls for a combination of treatment of the cause (obstruction of the urinary tract), adequate life-supporting care, and appropriate antibiotic therapy (2). In such a situation, it is recommended that urologists collaborate with intensive care and infectious disease specialists for the best management of the patient.

5.5.1 Preventive measures of proven or probable efficacy (9,10)
The most effective methods to prevent nosocomial urosepsis are the same as those used to prevent other nosocomial infections:

• Isolation of all patients infected with multi-resistant organisms to avoid cross-infection.
• Prudent use of antimicrobial agents for prophylaxis and treatment of established infections, to avoid selection of resistant strains. Antibiotic agents should be chosen according to the predominant pathogens at a given site of infection in the hospital environment.
• Reduction in hospital stay. It is well known that long inpatient periods before surgery lead to a greater incidence of nosocomial infections.
• Early removal of indwelling urethral catheters, as soon as allowed by the patient's condition. Nosocomial UTIs are promoted by bladder catheterisation as well as by ureteral stenting (11). Antibiotic prophylaxis does not prevent stent colonisation, which appears in 100% of patients with a permanent ureteral stent and in 70% of those temporarily stented.
• Use of closed catheter drainage and minimisation of breaks in the integrity of the system, e.g. for urine sampling or bladder wash-out.
• Use of least-invasive methods to release urinary tract obstruction until the patient is stabilised.
• Attention to simple everyday techniques to assure asepsis, including the routine use of protective, disposable gloves, frequent hand disinfection, and using infectious disease control measures to prevent cross-infections.

5.5.2 Appropriate perioperative antimicrobial prophylaxis
For appropriate perioperative antimicrobial prophylaxis, see Section 15. The potential side effects of antibiotics must be considered before their administration in a prophylactic regimen.

5.5.3 Preventive measures of debatable efficacy
• Instillation of antibiotic or antiseptic drugs into catheters and drainage bags.
• Use of urinary catheters coated with antibiotics or silver.

5.5.4 Ineffective or counterproductive measures
• Continuous or intermittent bladder irrigations with antibiotics or urinary antiseptics that increase the risk of infection with resistant bacteria (9,12).
• Routine administration of antimicrobial drugs to catheterised patients, which reduces the incidence of bacteriuria only for a few days and increases the risk of infection with multi-resistant bacteria (9,12). Its use may be reserved for immunosuppressed patients.

|                                  | 2. Intensified insulin therapy |
5.7.2 **Relief of obstruction**
Drainage of any obstruction in the urinary tract and removal of foreign bodies, such as urinary catheters or stones, should lead to resolution of symptoms and recovery. These are key components of the strategy. This condition is an absolute emergency.

5.7.3 **Antimicrobial therapy**
Empirical initial treatment should provide broad antimicrobial coverage and should later be adapted on the basis of culture results. The dosage of the antibiotic substances is of paramount importance in patients with sepsis syndrome and should generally be high, with the exception of patients in renal failure. Antimicrobials must be administered not later than 1 h after clinical assumption of sepsis (see algorithm). The antibacterial treatment options are summarised in Appendix 16.1 and 16.2.

5.7.4 **Adjunctive measures (12,13)**
The management of fluid and electrolyte balance is a crucial aspect of patient care in sepsis syndrome; particularly when the clinical course is complicated by shock. The use of human albumin is debatable. Early goal-directed therapy has been shown to reduce mortality (14). Volaemic expansion and vasopressor therapy have a considerable impact on the outcome. Early intervention with appropriate measures to maintain adequate tissue perfusion and oxygen delivery by prompt institution of fluid therapy, stabilisation of arterial pressure, and providing sufficient oxygen transport capacity are highly effective.

   Hydrocortisone (with a debate on dosage) is useful in patients with relative insufficiency in the pituitary gland-adrenal cortex axis (adrenocorticotropic test) (15).
   
   Tight blood glucose control by administration of insulin doses up to 50 U/h is associated with a reduction in mortality (16).
   
   Current evidence does not support the use of human recombinant activated protein C in adults and children with severe sepsis and septic shock (17).

   The best strategy has been summarised and graded according to a careful evidence-based methodology in the recently published ‘Surviving Sepsis Guidelines’ (18).

5.8 **Conclusion**
Sepsis syndrome in urology remains a severe situation with a mortality rate as high as 20-40%. A recent campaign, ‘Surviving Sepsis Guidelines’, aimed at reducing mortality by 25% in the next few years has been published recently (18). Early recognition of the symptoms may decrease the mortality by timely treatment of urinary tract disorders, e.g. obstruction, or urolithiasis. Adequate life-support measures and appropriate antibiotic treatment provide the best conditions for improving patient survival. The prevention of sepsis syndrome is dependent on good practice to avoid nosocomial infections and using antibiotic prophylaxis and therapy in a prudent and well-accepted manner.

6. CATHETER-ASSOCIATED UTIs

Based on the EAU guidelines published in 2007 (ISBN-13:978-90-70244-59-0), the following text presents the findings of a comprehensive update produced as a collaborative effort by the ESIU (a full EAU section office), the Urological Association of Asia, the Asian Association of UTI/STD, the Western Pacific Society for Chemotherapy, the Federation of European Societies for Chemotherapy and Infection, and the International Society of Chemotherapy for Infection and Cancer. This text was recently published as “The European and Asian guidelines on management and prevention of catheter-associated urinary tract infections” (1). Since the complete document is available online, only the abstract and a summary of the recommendations are presented here.

6.1 Abstract

We surveyed the extensive literature regarding the development, therapy and prevention of catheter-associated UTIs (CAUTIs). We systematically searched for meta-analyses of randomised controlled trials available in Medline, and gave preference to the Cochrane Central Register of Controlled Trials, and also considered other relevant publications, rating them on the basis of their quality. Studies were identified through a PubMed search. The recommendations of the studies, rated according to a modification of the US Department of Health...
and Human Services (1992), give a close-to-evidence-based guideline for all medical disciplines, with special emphasis on urology, in which catheter care is an important issue.

The survey found that the urinary tract is the commonest source of nosocomial infection, particularly when the bladder is catheterised (LE: 2a). Most CAUTIs are derived from the patient’s own colonic flora (LE: 2b) and the catheter predisposes to UTI in several ways. The most important risk factor for the development of catheter-associated bacteriuria is the duration of catheterisation (LE: 2a). Most episodes of short-term catheter-associated bacteriuria are asymptomatic and are caused by a single organism (LE: 2a). Further organisms tend to be acquired by patients who are catheterised for > 30 days.

The clinician should be aware of two priorities: the catheter system should remain closed and the duration of catheterisation should be minimal (GR: A). The use of nurse-based or electronic reminder systems to remove unnecessary catheters can decrease the duration of catheterisation and the risk of CAUTI (LE: 2a). The drainage bag should be always kept below the level of the bladder and the connecting tube (GR: B). In case of short-term catheterisation, routine prophylaxis with systemic antibiotics is not recommended (GR: B). There are sparse data about antibiotic prophylaxis in patients on long-term catheterisation, therefore, no recommendation can be made (GR: C). For patients using intermittent catheterisation, routine antibiotic prophylaxis is not recommended (GR: B). Antibiotic irrigation of the catheter and bladder is of no advantage (GR: A). Healthcare workers should be constantly aware of the risk of cross-infection between catheterised patients. They should observe protocols on hand washing and the need to use disposable gloves (GR: A).

A minority of patients can be managed with the use of the non-return (flip) valve catheters, thus avoiding the closed drainage bag. Such patients may exchange the convenience of on-demand drainage with an increased risk of infection. Patients with urethral catheters in place for ≥ 10 years should be screened annually for bladder cancer (GR: C). Clinicians should always consider alternatives to indwelling urethral catheters that are less prone to causing symptomatic infection. In appropriate patients, suprapubic catheters, condom drainage systems and intermittent catheterisation are each preferable to indwelling urethral catheterisation (GR: B). While the catheter is in place, systemic antimicrobial treatment of asymptomatic catheter-associated bacteriuria is not recommended (GR: A), except for some special cases. Routine urine culture in an asymptomatic catheterised patient is also not recommended (GR: C) because treatment is in general not necessary. Antibiotic treatment is recommended only for symptomatic infection (GR: B). After initiation of empirical treatment, usually with broad-spectrum antibiotics based on local susceptibility patterns (GR: C), the choice of antibiotics might need to be adjusted according to urine culture results (GR: B). Long-term antibiotic suppressive therapy is not effective (GR: A).

### 7. UTIs IN CHILDREN

#### 7.1 Summary and recommendations

Urinary tract infection in children is a frequent health problem, with the incidence only a little lower than that of upper respiratory and digestive infections.

The incidence of UTI varies depending on age and sex. In the first year of life, mostly the first 3 months, UTI is more common in boys (3.7%) than in girls (2%), after which the incidence changes, being 3% in girls and 1.1% in boys. Paediatric UTI is the most common cause of fever of unknown origin in boys aged < 3 years. The clinical presentation of UTI in infants and young children can vary from fever to gastrointestinal and lower or upper urinary tract symptoms.

Investigation should be undertaken after two episodes of UTI in girls and one in boys (GR: B). The objective is to rule out the unusual occurrence of obstruction, vesicoureteric reflux (VUR) and dysfunctional voiding, e.g. as caused by a neuropathic disorder.

Chronic pyelonephritic renal scarring develops very early in life due to the combination of a UTI, intrarenal reflux and VUR. It sometimes arises *in utero* due to dysplasia. Although rare, renal scarring may lead to severe long-term complications such as hypertension and chronic renal failure.

VUR is treated with long-term prophylactic antibiotics (GR: B). Surgical re-implantation or endoscopic treatment is reserved for the small number of children with breakthrough infection (GR: B).

For treatment of UTI in children, short courses are not advised and therefore treatment is continued for 5-7 days and longer (GR: A). If the child is severely ill with vomiting and dehydration, hospital admission is required and parenteral antibiotics are given initially (GR: A).

#### 7.2 Background

The urinary tract is a common source of infection in children and infants. It represents the most common bacterial infection in children < 2 years of age (1) (LE: 2a). The outcome of a UTI is usually benign, but in early infancy, it can progress to renal scarring, especially when associated with congenital anomalies of the urinary tract. Delayed sequelae related to renal scarring include hypertension, proteinuria, renal damage and even chronic renal failure, which requires dialysis treatment in a significant number of adults (2) (LE: 2a).

The risk of UTI during the first decade of life is 1% in males and 3% in females (3). It has been suggested that 5% of schoolgirls and up to 0.5% of schoolboys undergo at least one episode of UTI during their school life. The incidence is different for children < 3 months of age, when it is more common in boys. The incidence of asymptomatic bacteriuria is 0.7-3.4% in neonates, 0.7-1.3% in infants < 3 months of age, and 0.2-0.8% in preschool boys and girls (3). The incidence of symptomatic bacteriuria is 0.14% in neonates, with a further increase to 0.7% in boys and 2.8% in girls aged < 6 months. The overall recurrence rate for the neonatal period has been reported to be 25% (3,4).
7.3 **Aetiology**
The common pathogenic sources are Gram-negative, mainly enteric, bacteria. Of these, *E. coli* is responsible for 90% of UTI episodes (5). Gram-positive bacteria (particularly enterococci and staphylococci) represent 5-7% of cases. Hospital-acquired infections show a wider pattern of aggressive bacteria, such as *Klebsiella, Serratia* and *Pseudomonas* sp. Groups A and B streptococci are relatively common in new-born infants (6). There is an increasing trend towards the isolation of *S. saprophyticus* in UTIs in children, although the role of this bacterium is still debatable (7).

7.4 **Pathogenesis and risk factors**
The urinary tract is a sterile space with an impermeable lining. Retrograde ascent is the most common mechanism of infection. Nosocomial infection and involvement as part of a systemic infection are less common (8).

Obstruction and dysfunction are among the most common causes of urinary infection. Phimosis predisposes to UTI (9,10) (LE: 2a). Enterobacteria derived from intestinal flora colonise the preputial sac, glandular surface and the distal urethra. Among these bacteria are strains of *E. coli* that express P fimbriae, which adhere to the inner layer of the preputial skin and to uroepithelial cells (11).

A wide variety of congenital urinary tract abnormalities can cause UTIs through obstruction, e.g. urethral valves, ureteropelvic junction obstruction or non-obstructive urinary stasis (e.g. prune belly syndrome, or VUR). More mundane but significant causes of UTIs include labial adhesion and chronic constipation (7).

Dysfunctional voiding in an otherwise normal child may result in infrequent bladder emptying aided by delaying manoeuvres, e.g. crossing legs, sitting on heels (12). Neuropathic bladder dysfunction (e.g. spina bifida, or sphincter dyssynergia) may lead to post-void residual urine and secondary VUR (4).

The link between renal damage and UTIs is controversial. The mechanism in obstructive nephropathy is self-evident, but more subtle changes occur when there is VUR. Almost certainly, the necessary components include VUR, intrarenal reflux and UTI. These must all work together in early childhood when the growing kidney is likely to be susceptible to parenchymal infection. Later on in childhood, the presence of bacteriuria seems irrelevant to the progression of existing scars or the very unusual formation of new scars. Another confounding factor is that many so-called scars are dysplastic renal tissue which develop in utero (13).

7.5 **Signs and symptoms**
Symptoms are non-specific, and vary with the age of the child and the severity of the disease. Epididymo-orchitis is extremely unusual. With scrotal pain and inflammation, testicular torsion has to be considered.

A UTI in neonates may be non-specific and with no localisation. In small children, a UTI may present with gastrointestinal signs, such as vomiting and diarrhoea. In the first weeks of life, 13.6% of patients with fever have a UTI (14). Rarely, septic shock is the presentation. Signs of UTI may be vague in small children, but later on, when they are older than 2 years, frequent voiding, dysuria and suprapubic, abdominal or lumbar pain may appear with or without fever.

7.6 **Classification**
UTIs may be classified as a first episode or recurrent, or according to severity (simple or severe). Recurrent UTI may be subclassified into three groups (8):

- **Unresolved infection**: subtherapeutic level of antimicrobial, non-compliance with treatment, malabsorption, resistant pathogens.
- **Bacterial persistence**: may be due to a nidus for persistent infection in the urinary tract. Surgical correction or medical treatment for urinary dysfunction may be needed.
- **Reinfection**: each episode is a new infection acquired from periurethral, perineal or rectal flora. From the clinical point of view, severe and simple forms of UTIs should be differentiated because to some extent the severity of symptoms dictates the degree of urgency with which investigation and treatment are to be undertaken (Table 7.1).

### Table 7.1: Clinical classification of UTIs in children

<table>
<thead>
<tr>
<th>Severe UTI</th>
<th>Simple UTI</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fever ≥ 39°C</td>
<td>Mild pyrexia</td>
</tr>
<tr>
<td>Persistent vomiting</td>
<td>Good fluid intake</td>
</tr>
<tr>
<td>Serious dehydration</td>
<td>Slight dehydration</td>
</tr>
<tr>
<td>Poor treatment compliance</td>
<td>Good treatment compliance</td>
</tr>
</tbody>
</table>
7.6.1 **Severe UTI**
Severe UTI is related to the presence of fever of \(\geq 39^\circ\text{C}\), the feeling of being ill, persistent vomiting, and moderate or severe dehydration.

7.6.2 **Simple UTI**
A child with a simple UTI may have only mild pyrexia, but is able to take fluids and oral medication. The child is only slightly or not dehydrated and has a good expected level of compliance. When a low level of compliance is expected, such a child should be managed as one with a severe UTI.

7.7 **Diagnosis**

7.7.1 **Physical examination**
It is mandatory to look for phimosis, labial adhesion, signs of pyelonephritis, epididymo-orchitis, and stigmata of spina bifida, e.g. hairy patch on the sacral skin. The absence of fever does not exclude the presence of an infective process.

7.7.2 **Laboratory tests**
The definitive diagnosis of infection in children requires a positive urine culture (8,15). Urine must be obtained under bacteriologically reliable conditions when undertaking a urine specimen culture (16). A positive urine culture is defined as the presence of > 100,000 cfu/mL of one pathogen. The urine specimen may be difficult to obtain in a child < 4 years old, and different methods are advised because there is a high risk of contamination (17,18).

7.7.2.1 **Collection of the urine**

7.7.2.1.1 Suprapubic bladder aspiration
Suprapubic bladder aspiration is the most sensitive method, even though urine may be obtained in 23-99% of cases (8,18).

7.7.2.1.2 Bladder catheterisation
Bladder catheterisation is also a very sensitive method, even though there is the risk of introduction of nosocomial pathogens (8,19).

7.7.2.1.3 Plastic bag attached to the genitalia
Prospective studies have shown a high incidence of false-positive results, ranging from 85 to 99% (8,18). It is helpful when the culture is negative (8,18) and has a positive predictive value of 15% (16). To obtain a urine sample in the best condition in children < 2 years of age (girls and uncircumcised boys without sphincteric control), it is better to use suprapubic bladder aspiration or bladder catheterisation. In older children with sphincteric control, MSU collection is possible and reliable (18).

7.7.2.2 **Quantification of bacteriuria**
The final concentration of bacteria in urine is directly related to the method of collection, diuresis, and method of storage and transport of the specimen (15). The classical definition of significant bacteriuria of > 10^5 cfu/mL is still used and depends on the clinical environment (15,17).

The presence of pyuria (> 5 leukocytes per field) and bacteriuria in a fresh urine sample reinforce the clinical diagnosis of UTI (17).

In boys, when the urine is obtained by bladder catheterisation, the urine culture is considered positive with > 10^6 cfu/mL. Even though Hoberman (20) has identified a microorganism in 65% of cases with colony counts between 10,000 and 50,000 cfu/mL, there was a mixed growth pattern suggesting contamination. In these cases, it is better to repeat the culture or to evaluate the presence of other signs, such as pyuria, nitrites or other biochemical markers (15). The collection of MSU or in a collecting bag of \(\geq 10^6\) cfu/mL is considered positive (16) (Table 7.2).

7.7.2.3 Other biochemical markers

The presence of other biochemical markers in a urine sample are useful to establish the diagnosis of UTI (8). The most frequent markers are nitrite and leukocyte esterase usually combined in a dipstick test.

7.7.2.3.1 Nitrite

Nitrite is the degradation product of nitrate in bacterial metabolism, particularly in Gram-negative bacteria. When an infection is caused by Gram-positive bacteria, the test may be negative (8,16). Limitations of the nitrite test include:

- not all uropathogens reduce nitrate to nitrite, e.g. *P. aeruginosa*, or enterococci;
- even nitrite-producing pathogens may show a negative test result, due to the short transit time in the bladder in cases of high diuresis and urine dilution, e.g. neonates;
- the nitrite test has a sensitivity of only 45-60%, but a very good specificity of 85-98% (8,17,21).

7.7.2.3.2 Leukocyte esterase

Leukocyte esterase is produced by the activity of leukocytes. The test for leukocyte esterase has a sensitivity of 48-86% and a specificity of 17-93% (8,17,20,21).

A combination of nitrite and leukocyte esterase testing improves sensitivity and specificity, but carries the risk of false-positive results (21).

The dipstick test has become useful to exclude rapidly and reliably the presence of a UTI, provided both nitrite and leukocyte esterase tests are negative. If the tests are positive, it is better to confirm the results in combination with the clinical symptoms and other tests (17,21).

Bacteriuria without pyuria may be found:

- in bacterial contamination;
- in colonisation (asymptomatic bacteriuria);
- when collecting a specimen before the onset of an inflammatory reaction.

In such cases, it is advisable to repeat the urinalysis after 24 h to clarify the situation. Even in febrile children with a positive urine culture, the absence of pyuria may cast doubt on the diagnosis of UTI. Instead, asymptomatic bacteriuria with a concomitant septic focus responsible for the febrile syndrome has to be considered.

Bacteriuria without pyuria is found in 0.5% of specimens. This figure corresponds well with the estimated rate of asymptomatic bacteriuria in childhood (20,22) (LE: 2a).

Pyuria without bacteriuria may be due to:

- incomplete antimicrobial treatment of UTI;
- urolithiasis and foreign bodies;
- infections caused by *M. tuberculosis* and other fastidious bacteria, e.g. Chlamydia trachomatis.

Thus, either bacteriuria or pyuria may not be considered reliable parameters to diagnose or exclude UTI. Their assessment can be influenced by other factors, such as the degree of hydration, method of specimen collection, mode of centrifugation, volume in which sediment is resuspended and subjective interpretation of results (23). However, according to Landau et al. (24), pyuria in febrile children is indicative of acute pyelonephritis.

For all of these reasons, in neonates and children < 6 months of age, either pyuria, bacteriuria or the nitrite test, separately, have minimal predictive value for UTI (25,26) (LE: 3). In contrast, the positive predictive value of significant Gram staining with pyuria is 85% (20) (LE: 2b). In older children, pyuria with a positive nitrite test is more reliable for the diagnosis of UTI, with a positive predictive value of 98%.

Combining bacteriuria and pyuria in febrile children, the findings of ≥ 10 WBC/mm³ and ≥ 50,000 cfu/mL in a specimen collected by catheterisation are significant for a UTI, and discriminate between infection and contamination (20,25).

7.7.2.3.3 C-reactive protein

Although non-specific in febrile children with bacteriuria, C-reactive protein seems to be useful in distinguishing between acute pyelonephritis and other causes of bacteriuria. It is considered significant at a concentration > 20 μg/mL.

7.7.2.3.4 Urinary N-acetyl-β-glucosaminidase

Urinary N-acetyl-β-glucosaminidase is a marker of tubular damage. It is increased in febrile UTI and may become a reliable diagnostic marker for UTIs, although it is also elevated in VUR (27).

7.7.2.3.5 IL-6

The clinical use of urinary concentrations of IL-6 in UTIs (28) is still at the research stage.
7.7.3  Imaging of the urinary tract
A gold standard imaging technique has to be cost-effective, painless, safe, and have minimal or no radiation, as well as have the ability to detect any significant structural anomaly. Current techniques do not fulfil all such requirements.

7.7.3.1  Ultrasonography
Ultrasonography (US) has become very useful in children because of its safety, speed and high accuracy in identifying the anatomy and size of the renal parenchyma and collecting system (29). It is subjective and therefore operator-dependent, and gives no information on renal function. However, scars can be identified, although not as well as with Tc-99m DMSA scanning (29,30) (LE: 2a). This technique has been shown to be very sensitive and excretory urography must be reserved only for when images need to be morphologically clarified (31) (LE: 2a).

7.7.3.2  Radionuclide studies
Tc-99m DMSA is a radiopharmaceutical that is bound to the basement membrane of proximal renal tubular cells; half of the dose remains in the renal cortex after 6 h. This technique is helpful in determining functional renal mass and ensures an accurate diagnosis of cortical scarring by showing areas of hypoactivity, which indicates lack of function. A UTI interferes with the uptake of this radiotracer by the proximal renal tubular cells, and may show areas of focal defect in the renal parenchyma. A star-shaped defect in the renal parenchyma may indicate an acute episode of pyelonephritis. A focal defect in the renal cortex usually indicates a chronic lesion or a renal scar (32-34) (LE: 2a).

Focal scarring or a smooth uniform loss of renal substance as demonstrated by Tc-99m DMSA is generally regarded as being associated with VUR (reflux nephropathy) (35,36). However, Rushton et al. (37) have stated that significant renal scarring may develop, regardless of the existence or absence of VUR. Ransley and Risdon (38) have reported that Tc-99m DMSA shows a specificity of 100% and sensitivity of 80% for renal scarring.

The use of Tc-99m DMSA scanning can be helpful in the early diagnosis of acute pyelonephritis. About 50-85% of children show positive findings in the first week. Minimal parenchymal defects, when characterised by a slight area of hypoactivity, can resolve with antimicrobial therapy (39,40). However, defects lasting > 5 months are considered to be renal scarring (41) (LE: 2a).

Tc-99m DMSA scans are considered more sensitive than excretory urography and US in the detection of renal scars (42-45). It remains questionable whether radionuclide scans can substitute for echography as a first-line diagnostic approach in children with a UTI (46,47).

7.7.3.3  Cystourethrography
7.7.3.3.1 Conventional voiding cystourethrography
Voiding cystourethrography (VCU) is the most widely used radiological exploration for the study of the lower urinary tract and especially of VUR. It is considered mandatory in the evaluation of UTIs in children < 1 year of age. Its main drawbacks are the risk of infection, the need for retrogrades filling of the bladder, and the possible deleterious effect of radiation on children (48). In recent years, tailored low-dose fluoroscopic VCU has been used for the evaluation of VUR in girls to minimise radiological exposure (49). VCU is mandatory in the assessment of febrile childhood UTI, even in the presence of normal US. Up to 23% of these patients may reveal VUR (50).

7.7.3.3.2 Radionuclide cystography (indirect)
This investigation is performed by prolonging the period of scanning after the injection of Tc-99m diethylene triamine pentaacetate (DTPA) or mercaptoacetyltriglycine (MAG-3) as part of dynamic renography. It represents an attractive alternative to conventional cystography, especially when following patients with reflux, because of its lower dose of radiation. Disadvantages are poor image resolution and difficulty in detecting lower urinary tract abnormalities (51,52).

7.7.3.3.3 Cystosonography
Contrast-material-enhanced voiding ultrasonography has been introduced for the diagnoses of VUR without irradiation (47,52). Further studies are necessary to determine the role of this new imaging modality in UTI.

7.7.3.4  Additional imaging
Excretory urography remains a valuable tool in the evaluation of the urinary tract in children, but its use in UTIs is debatable unless preliminary imaging has demonstrated abnormalities that require further investigation. The major disadvantages in infants are the risks of side effects from exposure to contrast media and radiation (53). However, the role of excretory urography is declining with the increasing technical superiority of CT (54) and
MRI. However, the indications for their use is still limited in UTI.

7.7.3.5 Urodynamic evaluation
When voiding dysfunction is suspected, e.g. incontinence, residual urine, increased bladder wall thickness, urodynamic evaluation with uroflowmetry, (video) cystometry, including pressure flow studies, and electromyography should be considered.

7.8 Schedule of investigation
Screening of infants for asymptomatic bacteriuria is unlikely to prevent pyelonephritic scar formation, as these usually develop very early in infancy. Only a minority of children with a UTI have an underlying urological disorder, but when present, such a disorder can cause considerable morbidity. Thus, after a maximum of two UTI episodes in a girl and one in a boy, investigations should be undertaken (Figure 7.1), but not in the case of asymptomatic bacteriuria (51-58). The need for DTPA/MAG-3 scanning is determined by the ultrasound findings, particularly if there is suspicion of an obstructive lesion.

7.9 Treatment
Treatment has four main goals:
1. elimination of symptoms and eradication of bacteriuria in the acute episode;
2. prevention of renal scarring;
3. prevention of a recurrent UTI;
4. correction of associated urological lesions.

7.9.1 Severe UTIs
A severe UTI requires adequate parenteral fluid replacement and appropriate antimicrobial treatment, preferably with cephalosporins (third generation). If a Gram-positive UTI is suspected by Gram stain, it is useful to administer aminoglycosides in combination with ampicillin or amoxicillin/clavulanate (59) (LE: 2a). Antimicrobial treatment has to be initiated on an empirical basis, but should be adjusted according to culture results as soon as possible. In patients with an allergy to cephalosporins, aztreonam or gentamicin may be used. When aminoglycosides are necessary, serum levels should be monitored for dose adjustment. Chloramphenicol, sulphonamides, tetracyclines, rifampicin, amphotericin B and quinolones should be avoided. The use of ceftriaxone must also be avoided due to its undesired side effect of jaundice.

A wide variety of antimicrobials can be used in older children, with the exception of tetracyclines (because of tooth staining). Fluorinated quinolones may produce cartilage toxicity (58), but if necessary, may be used as second-line therapy in the treatment of serious infections, because musculoskeletal adverse events are of moderate intensity and transient (60,61). For a safety period of 24-36 h, parenteral therapy should be administered. When the child becomes afebrile and is able to take fluids, he/she may be given an oral agent to complete the 10-14 days of treatment, which may be continued on an outpatient basis. This provides some advantages, such as less psychological impact on the child and more comfort for the whole family. It is also less expensive, well tolerated and eventually prevents opportunistic infections (20). The preferred oral antimicrobials are: trimethoprim (TMP), co-trimoxazole (TMP plus sulphamethoxazole), an oral cephalosporin,
or amoxycillin/clavulanate. However, the indications for TMP are declining in areas with increasing resistance.

In children < 3 years of age, who have difficulty taking oral medications, parenteral treatment for 7-10 days seems advisable, with similar results to those with oral treatment (62).

If there are significant abnormalities in the urinary tract (e.g. VUR, or obstruction), appropriate urological intervention should be considered. If renal scarring is detected, the patient will need careful follow-up by a paediatrician in anticipation of sequelae such as hypertension, renal function impairment, and recurrent UTI.

An overview of the treatment of febrile UTIs in children is given in Figure 7.2 and the dosing of antimicrobial agents is outlined in Table 7.3 (63).

**7.9.2 Simple UTIs**
A simple UTI is considered to be a low-risk infection in children. Oral empirical treatment with TMP, an oral cephalosporin or amoxycillin/clavulanate is recommended, according to the local resistance pattern. The duration of treatment in uncomplicated UTIs treated orally should be 5-7 days (64,65) (LE: 1b). A single parenteral dose may be used in cases of doubtful compliance and with a normal urinary tract (66) (LE: 2a). If the response is poor or complications develop, the child must be admitted to hospital for parenteral treatment (67).

**7.9.3 Prophylaxis**
If there is an increased risk of pyelonephritis, e.g. VUR, and recurrent UTI, low-dose antibiotic prophylaxis is recommended (68,69) (LE: 2a). It may also be used after an acute episode of UTI until the diagnostic work-up is completed. The most effective antimicrobial agents are: nitrofurantoin, TMP, cephalexin and cefaclor (68).

**7.10 Acknowledgement**
With our grateful thanks, the chapter on UTIs in children was updated also by Jorge Caffaratti Sfulcini, Paediatric Urology, Fundació Puigvert, Barcelona, Spain, as co-author.

8. **UTIs IN RENAL INSUFFICIENCY, TRANSPLANT RECIPIENTS, DIABETES MELLITUS AND IMMUNOSUPPRESSION**

8.1 **Summary and recommendations**

8.1.1 **Acute effects of UTI on the kidney**

In acute pyelonephritis, very dramatic changes can occur with focal reduction in perfusion on imaging and corresponding renal tubular dysfunction. However, if in the adult the kidney is normal beforehand, chronic renal damage is unlikely. There is no evidence that prolonged or intensive antibiotic treatment of acute pyelonephritis shortens the episode or prevents complications.

In diabetes mellitus, overwhelming infection can predispose to pyogenic infection with intrarenal perinephric abscess formation, emphysematous pyelonephritis, and rarely, a specific form of infective interstitial nephropathy. Papillary necrosis is a common consequence of pyelonephritis in patients with diabetes. Women are more prone to asymptomatic bacteriuria than men with diabetes, but in both sexes, progression to clinical pyelonephritis is more likely than in normal individuals. The risk factors for developing asymptomatic bacteriuria differ between type 1 and type 2 diabetes.

It is arguable that diabetic patients are susceptible to rapid progression of parenchymal infection. However, the clearance of asymptomatic bacteriuria should not be attempted if the intention is to prevent complications, notably acute pyelonephritis (GR: A).

8.1.2 **Chronic renal disease and UTI**

There are several factors of general potential importance that predispose to infection in uraemia, including the loss of several urinary defence mechanisms and a degree of immunosuppression. Typically, adult polycystic kidney disease (APCKD), gross VUR and end-stage obstructive uropathy harbour infective foci or promote ascending infection, but not invariably so. Clearly, severe UTI with accompanying bacteraemia can hasten progression of renal failure, but there is little evidence that vigorous treatment of lesser degrees of infection or prophylaxis will slow renal functional impairment once it is established (GR: C).

In patients with VUR and UTI in end-stage chronic renal failure, bilateral nephroureterectomy should only be undertaken as a last resort (GR: B).

8.1.2.1 **APCKD**

In patients with acute pyelonephritis and infected cysts (presenting as recurrent bacteraemia or local sepsis), treatment requires a long course of high-dose systemic fluoroquinolones, followed by prophylaxis. Bilateral
nephrectomy should be utilised as a last resort (GR: B).

8.1.2.2 **Calculi and UTI**
Management is similar to that for patients without renal impairment, i.e. to clear the stones if possible and to minimise antibiotic treatment if the calculus cannot be removed. Nephrectomy should be performed as a last resort, but even residual renal function may be of vital importance (GR: B).

8.1.2.3 **Obstruction of the urinary tract and UTI**
As in all other situations, the combination of obstruction and infection is dangerous and should be treated vigorously. Obstruction may be covert and require specific diagnostic tests, e.g. video-urodynamics, or upper urinary tract pressure flow studies.

8.1.3 **UTI in renal transplantation and immunosuppression**
The need to correct uropathy or to remove a potential focus of infection in an end-stage disease kidney is more pressing in patients enlisted for renal transplantation. Even so, the results of nephrectomy for a scarred or hydronephrotic kidney may be disappointing.

Immunosuppression is of secondary importance, although if this is extreme, it can promote persistent bacteriuria, which may become symptomatic. In the context of renal transplantation, UTI is very common, but immunosuppression is only one of many factors that are mainly classified as ‘surgical’.

HIV infection is associated with acute and chronic renal disease, possibly through the mechanisms of thrombotic microangiopathy and immune-mediated glomerulonephritis. Steroids, angiotensin-converting enzyme (ACE) inhibitors and highly active retroviral therapy appear to reduce progression to end-stage renal disease.

8.1.4 **Antibiotic treatment for UTI in renal insufficiency and after renal transplantation**
The principles of antibiotic treatment for UTI in the presence of renal impairment, during dialysis treatment and after renal transplantation are discussed in the text and summarised in Tables 8.1-8.4.

8.2 **Background**
Whenever UTI is present in patients with renal insufficiency, problems arise in both the treatment of infection and the management of renal disease. There are also important scientific issues to be considered concerning the cause, special susceptibilities, effects and complications of renal parenchymal infection, particularly in the immunosuppressed patient.

This part of the guidelines can be subdivided into four sections.

1. What are the acute effects of UTI on the kidney and do the lesions become chronic?
2. Does chronic renal disease progress more quickly as a result of infection, and do particular renal diseases predispose to UTI?
3. Are immunosuppressed patients prone to UTI, particularly in the context of renal transplantation? Is UTI a significant cause of graft failure?
4. Which problems arise in antibiotic therapy in patients with renal insufficiency and after renal transplantation?

8.3 **Acute effects of UTI on the kidney**
Some authors regard acute pyelonephritis as complicated because, in their view, it may cause renal scarring in a previously normal kidney (1,2) (LE: 2a). Pathologically, a similar process may occur in such fundamentally different situations as obstructive and reflux nephropathy, although the distribution and extent of the lesions may be different (3-5) (LE: 2a).

8.3.1 **VUR and intrarenal reflux**
The effects of VUR and intrarenal reflux on the renal parenchyma, and the contribution of ascending infection are still unresolved. Renal scarring can certainly be acquired as a result of these three factors, although, in almost all cases, this usually occurs very early in life. In this narrow age range, developmental renal dysplasia must be a major consideration in the pathogenesis of chronic pyelonephritis.

Although acute infection is important in the early stages of this disease, the status of either recurrent acute UTI or asymptomatic bacteriuria specifically in the progression of scar formation is tenuous. Prophylactic antibiotics therefore offer little benefit in preserving renal tissue in reflux nephropathy in older children and adults, even if the reflux has not already been successfully treated (6) (GR: A). However, further discussion of reflux nephropathy is beyond the scope of these guidelines.
8.3.2 **Obstructive neuropathy**

Obstruction occurring through a voiding disorder or supravesically causes renal tubular dysfunction and ultimately renal damage, mainly through the process of apoptosis. Infection enhances the process of parenchymal loss. In extreme cases, pyonephrosis, perinephric abscess and widespread systemic sepsis develop. Obstruction has to be cleared if infection is to be eradicated (7) (GR: A).

A detailed discussion of obstructive nephropathy is not appropriate here, but the kidney that is permanently damaged by any cause has less reserve to withstand the effects of reflux, obstruction and infection. In any circumstances, the combination of obstruction and infection is a surgical emergency and both must be relieved without delay. It is sometimes difficult to exclude an element of obstruction when discussing the pathogenesis of putative infective renal damage in the alleged normal kidney. Urinary calculi and pregnancy can cause urinary stasis and an intermittent increase in pressure in the upper urinary tract, which can cause subtle and persistent damage.

8.3.3 **Renal effects of severe UTI**

Severe infection can lead to renal functional impairment through sepsis, endotoxaemia, hypotension and poor renal perfusion, as a part of the process of multiorgan failure. The presence of renal calculi and diabetes mellitus further reduces host defences (8).

8.3.4 **Acute effects of UTI on the normal kidney**

The acute effects of UTI on the normal kidney are complex. They are worth reviewing because they may provide a lead in deciding how chronic changes can occur and therefore a basis for the development of guidelines on the prevention of renal damage.

*E. coli* is the most common of the Gram-negative bacteria that are isolated in the majority of patients with acute pyelonephritis. The proportion of infections caused by *E. coli* is lower in adults than children (69% vs. 80%) (9) (LE: 2b).

Virulent microorganisms cause direct cellular injury, usually after colonising the renal pelvis. Damage can also occur indirectly from the effects of inflammatory mediators. Metastatic infection rarely causes renal infection, which presents as cortical abscesses, and usually only in susceptible individuals (see the sections below on Diabetes mellitus and Immunosuppression) (10).

Bacterial infection in the urinary tract can induce fever and elevate acute phase reactants, such as C-reactive protein, and erythrocyte sedimentation rate (ESR). Bacterial infection also elicits immunoglobulin A and cytokine responses (11) (LE: 2b). In particular, serum levels of IL-6 and IL-8 are elevated (12,13) (LE: 2b).

Tissue damage is reflected by urinary secretion of tubular proteins and enzymes, such as α2-macroglobulin, β2-microglobulin and N-acetyl-β-D-glucosaminidase. In functional terms, there may be a loss of concentrating power that can persist in the long term (14,15) (LE: 2b). The fact that there is a serological immune response and bacteria become coated with antibodies to various antigenic components of the microorganism is regarded as evidence of an immune response, and therefore, of exposure to microorganisms that are potentially damaging to the renal parenchyma (16) (LE: 2b).

There are many identifiable factors relating to virulence of the bacterial cell and to its ability to adhere to the mucosa as a preliminary to invasion (17). For example, type 1 pili or fimbriae combine with mannose receptors on the uromucoid, which is part of the protective mucopolysaccharide layer found on uroepithelial cells lining the urinary tract. Type 2 or P fimbriae bind to glycolipids of the blood group substances that are secreted by the host urothelium. In practical terms, *E. coli*, which is pathological to the kidney, appears to express P (or pyelonephritis-associated) or type 2 fimbriae, at least in children in whom 90% of individuals with acute pyelonephritis express these bacteria, compared with a much smaller proportion of those who have had cystitis or asymptomatic bacteriuria (18) (LE; 2b).

Bacterial adhesion may be of variable benefit to the bacterium, because its attachment may mean that it is easier for host defence mechanisms to localise and abolish it (19). The cellular and humoral inflammatory host response is also a crucial part of host defences. Various cytokines (e.g., IL-6 and IL-8) are responsible for inducing leukocyte migration, and may be intrinsically deficient in converting asymptomatic bacterial colonisation to clinical infection.

Paradoxically, reduced adhesiveness can facilitate silent penetration into the renal parenchyma. In a Swedish study, a group of 160 patients who had recently suffered acute UTI all developed reduced concentrating power, even though a significant proportion (40%) did not develop a febrile illness. In the majority of these patients, the infiltrating bacteria had reduced adhesive characteristics, perhaps facilitating their penetration into the renal parenchyma and promoting more permanent structural and functional damage (15) (LE: 2b).

8.3.5 **Renal scarring**

The possible development of scarring, as a result of UTI in the absence of reflux, obstruction or calculi, is
controversial (20) (LE: 2a). It is agreed that dramatic reduction in renal perfusion and excretion can occur acutely and so-called ‘lobar nephronia’ has been demonstrated with the newer methods of imaging, such as CT or DMSA scanning, but not with standard intravenous urography (IVU).

A study has shown that 55% of patients with no pre-existing lesions developed acute parenchymal lesions during an episode of acute pyelonephritis (2) (LE: 2a). These lesions were found to have persisted after 3-6 months follow-up in 77% of patients (9) (LE: 3).

An earlier study by Alwall (21) has described 29 women who were followed for 20-30 years, with evidence of increasing renal damage and chronic pyelonephritis upon biopsy (LE: 3). That study would have used cruder diagnostic techniques, which might not have identified pre-existing disease, therefore, patients may have had renal damage initially. Over such a long period, it was impossible to exclude other causes of renal impairment and interstitial nephropathy, e.g. analgesic abuse. This important issue is clarified by a recent more critical study of DMSA scanning during the acute phase of acute pyelonephritis. In the study, 37 of 81 patients had one or more perfusion defects, of which, the majority resolved within 3 months. In lesions that persisted, further imaging invariably showed evidence of reflex or obstructive nephropathy that must have predated the acute infective episode (22) (LE: 2a).

In summary, small parenchymal scars demonstrated by modern imaging may develop as a result of acute non-obstructive pyelonephritis. However, such patients do not develop chronic renal failure and the scar is a very different lesion from the typical scar of reflux nephropathy. This is reflected in clinical experience. Thus, in acute pyelonephritis, IVU or DMSA scanning during an acute urinary infection can have alarming and dramatic results, but in practical terms the observed changes mostly resolve.

The poor correlation between the severity of the symptoms in an episode of acute pyelonephritis and the risk of permanent damage, which is very small, should discourage the clinician from prescribing excessive antibiotic treatment beyond that needed to suppress the acute inflammatory reaction (GR: A).

In future, the rare occurrence of renal damage apparently arising from acute or recurrent uncomplicated UTI may be prevented by targeting long-term treatment at selected patients. These patients will have been identified as having an intrinsic genetic defect in the host response of cytokine release to infection. Such a genetic defect would be even more important if a patient also had structural abnormalities that cause complicated UTI.

8.3.6 Specific conditions in which an acute UTI causes renal damage

There are several specific conditions in which acute UTI can cause renal damage.

8.3.6.1 Diabetes mellitus

Asymptomatic bacteriuria is common in diabetic women. In a prospective study of non-pregnant women with diabetes mellitus, 26% had significant bacteriuria (≥ 10^5 cfu/mL) compared with 6% of controls. Women with type 1 diabetes are particularly at risk if they have had diabetes for a long time or complications have developed, particularly peripheral neuropathy and proteinuria. Risk factors in patients with type 2 diabetes were old age, proteinuria, a low body mass index and a past history of recurrent UTIs (23) (LE: 2a).

Diabetes mellitus increases the risk of acute pyelonephritis from infection by Enterobacteriaceae That originate in the lower urogenital tract. Klebsiella infection is particularly common (25% compared with 12% in non-diabetics).

Asymptomatic bacteriuria is common in women with diabetes (though not in men). If left untreated, it may lead to renal functional impairment (24). The mechanism is ill-understood and, as in uncomplicated acute pyelonephritis, a direct causal link is dubious. Other subtle factors may be present, such as underlying diabetic nephropathy (25) and autonomic neuropathy that causes voiding dysfunction. Impaired host resistance is thought to predispose to persistence of nephropathogenic organisms, but specific evidence is lacking for the development of renal complications. Glycosuria inhibits phagocytosis and perhaps cellular immunity, and encourages bacterial adherence. However, diabetic women with asymptomatic bacteriuria can have good glycaemic control, but still show reduced urinary cytokine and leukocyte concentrations (although polymorph function is normal). Poor glycaemic control has not been shown to increase the risk of bacteriuria (26).

It has always been recognised that diabetic patients are particularly susceptible to rapid progression of renal parenchymal infection and ensuing complications. Until recently, there was no consensus on the questions of pre-emptive screening, treatment and prophylaxis of asymptomatic bacteriuria. However, these issues have been addressed in a placebo-controlled, double-blind randomised trial (27) (LE: 1b), which has concluded that treatment does not reduce complications, and diabetes should not therefore be regarded as an indication for screening or treatment of asymptomatic bacteriuria. The findings from this trial have been subsequently recognised in the guidelines published by the Infectious Diseases Society of America (IDSA) on the diagnosis and treatment of asymptomatic bacteriuria in general (28).

Diabetic patients are also prone to an under-reported and probably unusual form of infective interstitial nephritis, which sometimes includes infection by gas-forming organisms, with a high mortality (emphysematous
pyelonephritis) (29). This is characterised histologically by acute pyogenic infiltration with micro-abscesses and the development of acute renal failure. The origin of the organisms may be haematogenous. Even in the absence of obstruction, acute parenchymal infection may progress insidiously to form an intrarenal abscess that ruptures, which leads to a perinephric collection and a psoas abscess. The presentation can occasionally be indolent.

Papillary necrosis is common in diabetics, particularly in association with acute pyelonephritis. It is certainly associated with permanent renal parenchymal scarring, although it is difficult to exclude obstruction by the sloughed papillae as the cause of the nephropathy. Antibiotic prophylaxis for the treatment of asymptomatic bacteriuria is probably required (GR: C).

8.3.6.2 Tuberculosis
Tuberculosis can cause acute and chronic renal damage through bilateral renal infiltration. Rarely, this can lead to end-stage renal failure. However, a more subtle form of interstitial granulomatous disease can occur, which is sufficient to cause renal failure in the absence of fibrosis, calcification or obstruction (30,31) (LE: 3).

Tuberculosis and leprosy can cause renal damage through the development of amyloid and a form of proliferative glomerulonephritis (32,33) (LE: 2b). For more details see the EAU guidelines on genitourinary tuberculosis (34).

8.4 Chronic renal disease and UTI
There are good reasons why all uraemic patients should be prone to UTI, and why UTI should increase the rate of deterioration of renal function. The antibacterial properties of normal urine, due to urea or low pH and high osmolality, may be lost (35). Uraemic patients are also mildly immunosuppressed and the formation of protective uroepithelial mucus may be inhibited (36-38) (LE: 2b).

However, apart from a few exceptions, there is little evidence for a causal relationship between pre-existing chronic renal disease and persistent UTI (7). The results of removing a scarred or hydronephrotic kidney in the hope of curing infection are often disappointing.

The few exceptions include the following.

8.4.1 Adult dominant polycystic kidney disease (ADPKD)
UTI is a prominent complication of ADPKD, with symptomatic UTI being the presenting feature in 23-42% of patients, who are usually female (39). It may be difficult to obtain a positive culture on standard laboratory media, but pyuria is common, particularly in the later stages of disease progression. Acute pyelonephritis is common and may originate from pyogenic infection in the cysts (40) (LE: 3).

The efficacy of antibiotic treatment may depend on whether cysts are derived from proximal (active secretion) or distal tubules (passive diffusion) and on the lipid solubility of the agent used. Cephalosporins, gentamicin and ampicillin, which are standard treatments of acute pyelonephritis and require active transport, are often ineffective (41) (LE: 2b). Fluoroquinolones are generally the most effective (GR: A).

After transplantation, overall graft and patient survival rates do not differ between ADPKD and control groups (42) (LE: 2a). However, despite close monitoring of patients, UTI and septicaemic episodes are still a significant cause of morbidity, such that bilateral nephrectomy may be the only option.

Polycystic disease is not to be confused with acquired renal cystic disease of the end-stage kidney, which has no predisposition to UTI.

The issue of whether urological complications, including UTI, affect the progression of renal failure in polycystic disease or in any other renal pathology is controversial. Severe symptomatic UTIs may indicate an adverse prognosis, particularly in men with ADPKD.

8.4.2 Renal calculi
Nephrolithiasis, particularly from infective struvite stones, obstructive uropathy and gross reflux, clearly does promote infection, although not always. However, it is doubtful whether vigorous treatment of asymptomatic bacteriuria or even mild clinical UTI makes any difference to the progression of renal disease (43) (LE: 3).

It is disappointing that, as yet, few studies have provided long-term serial data that identify renal damage and its causal relationship with infection. In this respect, it is of some interest that a study of 100 patients who underwent reflux prevention surgery at least 20 years before has recently been published (44). It was concluded that even patients whose reflux prevention surgery had been successful were prone to recurrent UTI, hypertension and complications, which even occasionally included progressive renal scarring. Such consequences should at least inform the patient's decision in deciding between surgical and medical treatment of VUR.
8.5 UTI in renal transplantation

UTI is common after renal transplantation. Bacteriuria is present in 35-80% of patients, although the risk has been reduced by improvements in donation surgery, which have lowered the dose of immunosuppressive therapy and prophylactic antibiotics (45).

8.5.1 Donor organ infection

Early factors predisposing to UTI include infection in the transplanted kidney. Clearly, the organ donor should be screened for a variety of viral and bacterial infections. Detailed discussion of this process is beyond the limits of these guidelines. However, it must be acknowledged that the urinary tract of the cadaver donor is rarely investigated, even if the mid-stream urine (MSU) culture is positive. Antibiotics are given empirically, but usually the first suspicion of occurrence of a renal tract abnormality is raised during the organ donation operation. Under these circumstances, only the most obvious renal or ureteric abnormality will be detected. Very occasionally, organ donation will be abandoned at this late stage.

After the kidney is removed from its storage box, the effluent from the renal vein and surrounding fluid in the sterile plastic bags that contain the excised kidney should ideally be cultured because microorganisms are likely to have been introduced during the donation process. Bladder catheters and ureteric stents promote the loss of the glycosoaminoglycan layer from the uroepithelium, as well as providing a source of microorganisms within the mucous biofilm that covers the foreign body. Infection in the native kidney may worsen considerably as a result of maximum immunosuppression.

In renal transplant recipients, the following problems are most troublesome: papillary necrosis, particularly in diabetes mellitus (46), massive infective VUR, polycystic disease, and infective calculi. There is also concern about the increasing number of children with congenital uropathy, often associated with neuropathic bladder dysfunction and the sinister combination of intravesical obstruction, poor bladder compliance, residual urine, and VUR. A full urodynamic assessment, establishing a routine of intermittent self-catheterisation and any necessary bladder surgery must be completed well in advance of renal transplantation.

Urinary diversions and bladder augmentation and substitution have also been successfully completed in patients on dialysis treatment and after transplantation, although bacteriuria is common and may require antibiotic treatment (47).

In the first 3 months, UTI is more likely to be symptomatic with a high rate of relapse. Later on, there is a lower rate of pyelonephritis and bacteraemia, and a better response to antibiotics unless there are urological complications (e.g. fistula, or obstruction of the urinary tract). Infarction, either of the whole kidney or of a segment due to arterial damage, can promote UTI through bacterial colonisation of dead tissue. This often occurs by commensal or fastidious pathogens. The infection may be impossible to eradicate until the kidney, or at least the dead segment, is removed.

8.5.2 Graft failure

There are several potential mechanisms by which severe UTI can cause graft failure. There was an early suggestion that reflux into the graft could lead to pyelonephritis and parenchymal scarring. However, these findings have not been confirmed and most surgeons do not make a special effort to perform an antireflux anastomosis.

Infection can theoretically induce graft failure by three other mechanisms, such as by the direct effect of cytokines, growth factors (e.g. tumour necrosis factor [TNF]) and free radicals as part of the inflammation cascade (45). UTIs can also reactivate cytomegalovirus infection, which can lead to acute transplant rejection. Sometimes it can be very difficult to distinguish rejection from infection (48) (LE: 2b).

For many years, the polyomavirus type BK has been listed as a possible candidate for causing transplant ureteric stenosis. Improved detection of so-called ‘decoy cells’ in urine and of virus DNA by polymerase chain reaction has confirmed the causal relationship between infection and obstruction, but also with interstitial nephropathy progressing to graft loss in possibly 5% of recipients. The virus is susceptible to treatment with the antiviral agent cidofovir (49) (LE: 2a).

8.5.3 Kidney and whole-organ pancreas transplantation

Simultaneous kidney and whole-organ pancreas transplantation can present specific urological complications when the bladder is chosen for drainage of exocrine secretions. These may include recurrent UTI, chemical urethritis and bladder calculi of sufficient severity to warrant cystoenteric conversion. The risk of such complications is minimised if urodynamic abnormalities, e.g. obstruction, are identified and corrected well in advance of the transplant procedure (50) (LE: 3).

8.6 Antibiotic therapy in renal failure and transplant recipients

Much of the detailed information on antibiotic prescribing in renal failure is summarised in Tables 8.1-8.5 and Appendix 16.3. It is important to note that peritoneal dialysis and haemodialysis clear certain antibiotics, which
should either be avoided or given at much higher doses. Also, there are important interactions to consider between immunosuppressive agents and antibiotics.

**8.6.1 Treatment of UTI in renal transplant recipients**

The treatment of a symptomatic UTI is similar to treatment given to non-transplant patients. However, a short
course of treatment has yet to be established, and in most cases a 10-14-day course of treatment is given.

The choice of antibiotic is dictated by the special need for penetration into the renal parenchyma rather than for merely a ‘mucosal’ antibiotic. Fluoroquinolones seem to be particularly effective.

There is good evidence for the beneficial effects of treating asymptomatic bacteriuria in the first 6 months after renal transplantation (51) (LE: 2a). Patients must be investigated for surgical complications.

In most units, the combination of trimethoprim and sulphamethoxazole (co-trimoxazole) is effective in preventing UTI (52) (LE: 1b). It will also prevent Pneumocystis carinii pneumonia (PCP) and infection with other rare fastidious organisms. Low-dose antibiotic prophylaxis with co-trimoxazole has been recommended for 6 months after transplantation. This will cover the high-risk period when infection is more likely to be symptomatic and associated with acute graft impairment. At a low dose, adverse interactions with cyclosporin do not occur, although the higher dose advocated by some units results in synergistic nephrotoxicity with trimethoprim.

A number of other drug interactions need to be considered, e.g. gentamicin, co-trimoxazole and amphotericin B promote cyclosporin and tacrolimus toxicity. Rifampicin and erythromycin also interact with calcineurin inhibitors by increasing cytochrome p450 synthetase and inhibiting hepatic cyclosporin A metabolism.

In any patients with relapsing or recurrent infection, an anatomical cause, such as a urological complication in the transplant kidney or recipient bladder dysfunction, must be considered and treated vigorously.

8.6.2 Fungal infections
Candidal infections can occur in any immunosuppressed patient, but are more common in diabetic patients and those with chronic residual urine and in whom there is an indwelling catheter or stent. It is wise to treat all patients with antifungal agents (fluconazole, amphotericin B plus flucytosine) even when they are asymptomatic. Removal of the catheter or stents is usually necessary (GR: B).

8.6.3 Schistosomiasis
Schistosomiasis is a familiar problem for patients treated for end-stage renal failure from locations where the disease is endemic. Renal transplantation is possible, even when live donors and recipients have active lesions, provided they are treated. Combined medication (praziquantil and oxaminoquine) is recommended for 1 month. In a trial that compared infected patients with those free of schistosomiasis, there was no difference between the incidence of acute and chronic rejection. However, UTI and urological complications occurred in the infected group and a higher cyclosporin dose was required. Despite this, however, it was concluded that active schistosomiasis did not preclude transplantation (53) (LE: 3). For further details on schistosomiasis in genitourinary tract infections see Bichler et al. (54).

8.7 Immunosuppression
It is well known that viral and fungal infections are common in immunosuppressed patients.

8.7.1 Human immunodeficiency virus (HIV) infection
HIV infection can lead to acute renal failure through non-specific severe systemic illness, and to chronic renal failure through a variety of nephropathies. These include HIV-induced thrombotic microangiopathy, immune-mediated glomerulonephritis and nephropathy due to virus-induced cellular damage, primarily to the glomerular epithelial cell. Combination therapy using corticosteroids, ACE inhibitors and highly active antiretroviral therapy seems to delay and prevent progression of nephropathy, although evidence from randomised trials is not available (55). HIV infection is therefore no longer a contraindication to renal replacement therapy.

The place of immunosuppression per se in the development of UTI remains unresolved (56). Patients with end-stage renal failure are generally not particularly susceptible to the usual Gram-negative urinary pathogens, although they may acquire unusual and granulomatous infections. Patients have evidence of reduced cellular and humoral immunity.

However, the situation is a little clearer in male patients with HIV and AIDS, in whom there is a close relationship between CD4 counts and the risk of bacteriuria, particularly in patients whose counts are < 200 cells/mL (57). About 40% of patients with bacteriuria are asymptomatic. In these patients, PCP prophylaxis of the type used in transplant patients may not reduce the rate of bacteriuria, perhaps due to the previous development of resistant organisms.

8.7.2 Viral and fungal infections
Viral and fungal infections are relatively common in immunosuppressed patients.

8.8.1 Further reading
Antibiotic prescribing in renal failure: evidence base of guidelines. Information has been derived from the following standard reference sources:

9. URETHRITIS

9.1 Epidemiology
From a therapeutic and clinical point of view, gonorrhoeal urethritis has to be differentiated from non-specific urethritis. In Central Europe, non-specific urethritis is much more frequent than gonorrhoeal urethritis. There is a correlation between promiscuity and low socioeconomic status and the frequency of infections due to Neisseria gonorrhoeae and C. trachomatis. Infection is spread by sexual contact.

9.2 Pathogens
Pathogens include N. gonorrhoeae, C. trachomatis, Mycoplasma genitalium and Trichomonas vaginalis. The frequency of the different species varies between patient populations (1-5). Mycoplasma hominis probably does not cause urethritis, and Ureaplasma urealyticum is an infrequent cause. In most cases, clinical evidence of Mycoplasma or Ureaplasma is caused by asymptomatic colonisation of the urogenital tract.

9.3 Route of infection and pathogenesis
Causative agents either remain extracellularly on the epithelial layer or penetrate into the epithelium (N. gonorrhoeae and C. trachomatis) and cause pyogenic infection. Although arising from urethritis, chlamydiae and gonococci can spread further through the urogenital tract to cause epididymitis in men or cervicitis, endometritis and salpingitis in women. Recent evidence has suggested that Myc. genitalium can also cause cervicitis and pelvic inflammatory disease in women (6) (LE: 3).

9.4 Clinical course
Mucopurulent or purulent discharge, alguria, dysuria and urethral pruritus are symptoms of urethritis. However, many infections of the urethra are asymptomatic.

9.5 Diagnosis
A Gram stain of a urethral discharge or a urethral smear that shows more than five leukocytes per high power field (× 1,000) and eventually, gonococci located intracellularly as Gram-negative diplococci, indicate pyogenic urethritis (7) (LE: 3, GR: B). The Gram stain is the preferred rapid diagnostic test for evaluating urethritis. It is highly sensitive and specific for documenting urethritis and the presence or absence of gonococcal infection. A positive leukocyte esterase test or > 10 leucocytes per high power field (× 400) in the first voiding urine specimen is diagnostic. In all patients with urethritis, and when sexual transmission is suspected, the aim should be to identify the pathogenic organisms. If an amplification system is used for identifying the pathogens, the first voiding urine specimen can be taken instead of a urethral smear. Trichomonas sp. can usually be identified microscopically.
9.6  Therapy

9.6.1  Treatment of gonorrhoeal urethritis

The following guidelines for therapy comply with the recommendations of the US Centers for Disease Control and Prevention (8-10). The following antimicrobials can be recommended for the treatment of gonorrhoea:

As first-choice treatment
- ceftriaxone, 1 g intramuscularly (with local anaesthetic) as a single dose;
- azithromycin, 1 g orally as a single dose.

Alternative regimens
- ciprofloxacin, 500 mg orally as single dose;
- ofloxacin, 400 mg orally as single dose;
- levofloxacin, 250 mg orally as single dose.

Note that fluoroquinolones are contraindicated in adolescents (< 18 years) and pregnant women.

As a result of the continuous spread of fluoroquinolone-resistant N. gonorrhoeae, this class of antibiotics is no longer recommended for the treatment of gonorrhoea in the United States (11). In Europe, knowledge of local susceptibility patterns is mandatory for the correct treatment of gonorrhoeal urethritis.

Because gonorrhoeae is frequently accompanied by chlamydial infection, an active antichlamydial therapy should be added.

9.6.2  Treatment of non-gonorrhoeal urethritis

The following treatment has been successfully applied to non-gonorrhoeal urethritis:

<table>
<thead>
<tr>
<th>As first choice of treatment:</th>
<th>LE</th>
<th>GR</th>
</tr>
</thead>
<tbody>
<tr>
<td>azithromycin, 1 g orally as single dose</td>
<td>1b</td>
<td>A</td>
</tr>
<tr>
<td>doxycycline, 100 mg orally twice daily for 7 days</td>
<td>1b</td>
<td>A</td>
</tr>
<tr>
<td>As second choice of treatment:</td>
<td></td>
<td></td>
</tr>
<tr>
<td>erythromycin base, 500 mg orally four times daily for 14 days</td>
<td>1b</td>
<td>A</td>
</tr>
<tr>
<td>erythromycin ethylsuccinate, 800 mg orally four times daily for 7 days</td>
<td>1b</td>
<td>A</td>
</tr>
<tr>
<td>ofloxacin, 300 mg orally twice daily for 7 days</td>
<td>1b</td>
<td>A</td>
</tr>
<tr>
<td>levofloxacin, 500 mg orally once daily for 7 days</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Doxycycline and azithromycin are considered to be equally effective in the treatment of chlamydial infections, however, infections with Myc. genitalium may respond better to azithromycin (12). Erythromycin is less effective and causes more side effects. In pregnant women, fluoroquinolones and doxycycline are contraindicated, therefore, besides erythromycin and azithromycin, a regimen with amoxicillin 500 mg three times daily for 7 days is also recommended.

If therapy fails, one should consider treating infections by T. vaginalis and/or Mycoplasma with a combination of metronidazole (2 g orally as single dose) and erythromycin (500 mg orally four times daily for 7 days). As in other STDs, the treatment of sexual partners is necessary.

9.7  Follow-up and prevention

Patients should return for evaluation if symptoms persist or recur after completion of therapy. Patients should be instructed to abstain from sexual intercourse until 7 days after therapy is initiated, provided their symptoms have resolved and their sexual partners have been adequately treated. Persons who have been diagnosed with a new STD should receive testing for other STDs, including syphilis and HIV.

10. BACTERIAL PROSTATITIS

10.1 Summary and recommendations
Bacterial prostatitis is a disease entity diagnosed clinically and by evidence of inflammation and infection localised to the prostate. According to the duration of symptoms, bacterial prostatitis is described as either acute or chronic, when symptoms persist for at least 3 months. It is recommended that European urologists use the classification suggested by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) of the National Institutes of Health (NIH), in which bacterial prostatitis with confirmed or suspected infection is distinguished from chronic pelvic pain syndrome (CPPS).

Acute bacterial prostatitis can be a serious infection. Parenteral administration of high doses of a bactericidal antibiotic is usually required, which may include a broad-spectrum penicillin, a third-generation cephalosporin, or a fluoroquinolone. All of these agents can be combined with an aminoglycoside for initial therapy. Treatment is required until there is defervescence and normalisation of infection parameters (LE: 3, GR: B). In less severe cases, a fluoroquinolone may be given orally for 10 days (LE: 3, GR: B).

In chronic bacterial prostatitis, and if infection is strongly suspected in CPPS, preferably a fluoroquinolone should be given for at least 4 weeks. In case of fluoroquinolones resistance or adverse reactions, trimethoprim can be given orally for a period of 4 to 12 weeks after the initial diagnosis. The patient should then be reassessed and antibiotics only continued if pre-treatment cultures are positive and/or the patient has reported positive effects from the treatment. A total treatment period of 4-6 weeks is recommended (LE: 3, GR: B).

Patients with CPPS are treated empirically with numerous medical and physical modalities. The management of pain and other related symptoms are covered in the EAU Guidelines on Chronic Pelvic Pain (1).

10.2 Introduction and definition
Traditionally, the term prostatitis has included both acute and chronic bacterial prostatitis, in which an infective
origin is accepted, and the term prostatitis syndrome or, more recently, CPPS, in which no infective agent can be found and whose origin is multifactorial and in most cases obscure.

Prostatitis and CPPS are diagnosed by symptoms and evidence of inflammation and infection localised to the prostate (2). A causative pathogen, however, is detected by routine methods in only 5-10% of cases (3), and for whom antimicrobial therapy therefore has a rational basis. The remainder of patients are treated empirically with numerous medical and physical modalities. However, recent improvement in classification and application of modern methods, including molecular biology, should allow proper systematisation of treatment (4-6).

This chapter reviews documented or suspected bacterial infections of the prostate.

### 10.3 Diagnosis

#### 10.3.1 History and symptoms

According to the duration of symptoms, bacterial prostatitis is described as either acute or chronic, the latter being defined by symptoms that persist for at least 3 months (4-6). The predominant symptoms are pain at various locations and LUTS (Tables 10.2 and 10.3) (7-9). Chronic bacterial prostatitis is the most frequent cause of recurrent UTI in men (10).

- Frequent need to urinate
- Difficulty urinating, e.g. weak stream and straining
- Pain on urination, or that increases with urination

*Adapted from Alexander et al. (9).

#### 10.3.1.1 Symptom questionnaires

Symptoms appear to have a strong basis for use as a classification parameter in bacterial prostatitis as well as in CPPS (11). Prostatitis symptom questionnaires have therefore been developed for the quantification of symptoms (11,12). They include the Chronic Prostatitis Symptom Index (CPSI), which was recently developed by the International Prostatitis Collaborative Network (IPCN), initiated by the NIH (USA) (13).

Although the CPSI has been validated, to date, its benefit in clinical studies is still uncertain. The questionnaire contains four questions regarding pain or discomfort, two regarding urination, and three related to quality of life (see Appendix 16.5).

#### 10.3.2 Clinical findings

In acute prostatitis, the prostate may be swollen and tender on digital rectal examination (DRE). Prostatic
massage is contraindicated. Otherwise, the prostate is usually normal on palpation. An essential consideration in the clinical evaluation is to exclude prostatic abscesses. In case of lasting symptoms ("chronic prostatitis" symptoms) CPPS as well as other urogenital and ano-rectal disorders must be taken into consideration.

Symptoms of chronic prostatitis or CPPS can mask prostate tuberculosis. Pyospermia and hematospermia in men in endemic regions or with a history of tuberculosis should be investigated for urogenital tuberculosis.

10.3.3 Urine cultures and expressed prostatic secretion
The most important investigations in the evaluation of the patient with acute prostatitis is mid-stream urine culture. In chronic bacterial prostatitis, a quantitative bacteriological localisation cultures and microscopy of the segmented urine and of expressed prostatic secretion (EPS), as described by Meares and Stamey (2) (see Appendix 16.6).

The Enterobacteriaceae, especially *E. coli*, are the predominant pathogens in acute bacterial prostatitis (Table 10.4) (14). In chronic bacterial prostatitis, the spectrum of strains is wider. The significance of intracellular bacteria, such as *C. trachomatis*, is uncertain (15). In patients with immune deficiency or HIV infection, prostatitis may be caused by fastidious pathogens, such as *M. tuberculosis*, *Candida* sp. and rare pathogens, such as *Coccidioides immitis, Blastomyces dermatitidis*, and *Histoplasma capsulatum* (16). In case of suspected prostate tuberculosis, the urine should be investigated for *Mycobacterium* spp by PCR technique.

10.3.4 Prostate biopsy
Perineal biopsies cannot be recommended as routine work-up and should be reserved only for research purposes. Transrectal prostate biopsy is not advisable in bacterial prostatitis (LE: 4; GR: C).

10.3.5 Other tests
Transrectal ultrasound (TRUS) may reveal intraprostatic abscesses, calcification in the prostate, and dilatation of the seminal vesicles but is unreliable and cannot be used as a diagnostic tool in prostatitis (17).

10.3.6 Additional investigations
10.3.6.1 Ejaculate analysis
An analysis of the ejaculate is not recommended for microbiological investigation due to the low sensitivity and specificity compared to the 2- or 3-glass tests. Ejaculate analysis is however frequently involved as part of the investigation of a generalised male accessory gland infection (MAGI) and it provides information about sperm quality. The EAU working group believes that guidelines on prostatitis should not contain a set of differential diagnostic examinations. An experienced urologist should decide which investigations are relevant for each individual patient. Bladder outflow and urethral obstruction should always be considered and ruled out by uroflowmetry, retrograde urethrography, or endoscopy.

10.3.6.2 Prostate Specific Antigen (PSA)
PSA is often increased in acute bacterial prostatitis and other urogenital infections. If a patient has elevated PSA and evidence of prostatic inflammation, serum PSA will normalise after antimicrobial treatment for 4
weeks in about 50% of patients (18). A delay of at least 3 months should be allowed before it can be assumed that a stable level of PSA has been reached. Measurement of free and total PSA adds no practical diagnostic information in prostatitis (19).

10.4 Treatment
10.4.1 Antibiotics
Antibiotics are life-saving in acute bacterial prostatitis and recommended in chronic bacterial prostatitis.

Acute bacterial prostatitis is a serious infection with fever, intense local pain, and general symptoms. Parenteral administration of high doses of bactericidal antibiotics, such as a broad-spectrum penicillin, a third-generation cephalosporin or a fluoroquinolone, should be administered. For initial therapy, any of these antibiotics may be combined with an aminoglycoside. After defervescence and normalisation of infection parameters, oral therapy can be substituted and continued for a total of 2-4 weeks (20).

The recommended antibiotics in chronic bacterial prostatitis, together with their advantages and disadvantages, are listed in Table 10.7 (21). Fluoroquinolones, such as ciprofloxacin and levofloxacin, are considered drugs of choice because of their favourable pharmacokinetic properties (21) (LE: 2b, GR: B), their generally good safety profile, and antibacterial activity against Gram-negative pathogens, including P. aeruginosa. In addition, levofloxacin is active against Gram-positive and atypical pathogens, such as C. trachomatis and genital mycoplasmas (LE: 2b, GR: B).

The duration of antibiotic treatment is based on experience and expert opinion and is supported by many clinical studies (22). In chronic bacterial prostatitis antibiotics should be given for 4-6 weeks after initial diagnosis. Relatively high doses are needed and oral therapy is preferred (21,22) (LE: 3, GR: B). If intracellular bacteria have been detected or are suspected, tetracyclines or erythromycin should be given (21,23) (LE: 2b, GR: B).

10.4.2 **Intraprostatic injection of antibiotics**

This treatment has not been evaluated in controlled trials and should not be considered (24,25).

10.4.3 **Drainage and surgery**

Approximately 10 per cent of men with acute prostatitis will experience urinary retention (26) which can be managed by suprapubic, intermittent or indwelling catheterisation. Suprapubic cystostomy placement is however generally recommended. The use of catheterisation without evidence of retention may increase the risk of progression to chronic prostatitis (27). Alpha-blocker treatment has also been recommended, but clinical evidence of benefit is poor.

In case of prostatic abscess, both drainage and conservative treatment strategies appear feasible (28). The size may matter. In one study conservative treatment was successful if the abscess cavities were smaller than 1 cm in diameter, while larger abscesses were better treated by single aspiration or continuous drainage (29). Surgery should be avoided in the treatment of bacterial prostatitis.

11. EPIDIDYMITIS AND ORCHITIS

11.1 Summary and recommendations
Orchitis and epididymitis are classified as acute or chronic processes according to the onset and clinical course. The most common type of orchitis, mumps orchitis, develops in 20-30% of post-pubertal patients with mumps virus infection. If mumps orchitis is suspected, a history of parotitis and evidence of IgM antibodies in the serum supports the diagnosis.

Epididymitis is almost always unilateral and relatively acute in onset. In young males it is associated with sexual activity and infection of the consort (LE: 3). The majority of cases in sexually active males aged < 35 years are due to sexually transmitted organisms, whereas in elderly patients, it is usually due to common urinary pathogens (LE: 3). Epididymitis causes pain and swelling, which begins in the tail of the epididymis, and may spread to involve the rest of the epididymis and testicular tissue. The spermatic cord is usually tender and swollen. It is imperative for the physician to differentiate between epididymitis and spermatic cord torsion as soon as possible using all available information. The microbial aetiology of epididymitis can usually be determined by examination of a Gram stain of a urethral smear and/or an MSU for the detection of Gram-negative bacteriuria (LE: 3). A urethral swab and MSU should be obtained for microbiological investigation before antimicrobial therapy (GR: C). Antimicrobials should be selected on the empirical basis
that in young, sexually active men, *C. trachomatis* is usually causative, and that in older men, the most common uropathogens are involved. Fluoroquinolones with activity against *C. trachomatis* (e.g. ofloxacin and levofloxacin), should be the drugs of first choice. If *C. trachomatis* has been detected, treatment could also be continued with doxycycline, 200 mg/day, for a total of at least 2 weeks. Macrolides may be used as alternative agents (GR: C). Supportive therapy includes bed rest, up positioning of the testes and anti-inflammatory therapy. In case of *C. trachomatis* epididymitis, the sexual partner should also be treated (GR: C). Abscess-forming epididymitis or orchitis needs surgical treatment. Chronic epididymitis can sometimes be the first clinical manifestation of urogenital tuberculosis.

### 11.2 Definition and classification

Epididymitis, inflammation of the epididymis, causes pain and swelling which is almost always unilateral and relatively acute in onset. In some cases, the testes are involved in the inflammatory process (epididymo-orchitis). On the other hand, inflammatory processes of the testicle, especially virally induced orchitis, often involve the epididymis.

Orchitis and epididymitis are classified as acute or chronic processes according to the onset and clinical course. Chronic disease with induration develops in 15% of acute epididymitis cases. In the case of testicular involvement, chronic inflammation may result in testicular atrophy and the destruction of spermatogenesis (1,2).

### 11.3 Incidence and prevalence

There are no new data available concerning the incidence and prevalence of epididymitis. According to older data, acute epididymitis has been a major cause for admission to hospitals of military personnel (2) (LE: 3). Acute epididymitis in young men is associated with sexual activity and infection of the consort (3) (LE: 3).

The most common type of orchitis, mumps orchitis, develops in 20-30% of post-pubertal patients with mumps virus infection. The incidence depends upon the vaccination status of the population (4). Primary chronic orchitis is a granulomatous disease, and a rare condition with uncertain aetiology that has been reported in about 100 cases in the literature (5).

### 11.4 Morbidity

Complications in epididymo-orchitis include abscess formation, testicular infarction, testicular atrophy, development of chronic epididymal induration and infertility (2).

Epididymitis caused by sexually transmitted organisms occurs mainly in sexually active males aged < 35 years (2,6) (LE: 3). The majority of cases of epididymitis are due to common urinary pathogens, which are also the most common cause of bacteriuria (2,6) (LE: 3). Bladder outlet obstruction and urogenital malformations are risk factors for this type of infection.

### 11.5 Pathogenesis and pathology

Typically, in epididymitis due to common bacteria and sexually transmitted organisms, the infection is spread from the urethra or bladder. In non-specific granulomatous orchitis, autoimmune phenomena are assumed to trigger chronic inflammation (5,7). Paediatric orchitis and mumps orchitis are of haematogenous origin (7).

Epididymo-orchitis is also seen in systemic infections such as tuberculosis, lues, brucellosis and cryptococcus disease.

### 11.6 Diagnosis

In acute epididymitis, the inflammation and swelling usually begin in the tail of the epididymis, and may spread to involve the rest of the epididymis and testicular tissue. The spermatic cord is usually tender and swollen. All men with epididymitis that is caused by sexually transmitted organisms have a history of sexual exposure, and the organisms can lie dormant for months before the onset of symptoms. If the patient is examined immediately after undergoing urinalysis, urethritis and urethral discharge may be missed because WBC and bacteria have been washed out of the urethra during urination.

The microbial aetiology of epididymitis can usually be determined by examination of a Gram stain of a urethral smear and/or an MSU for the detection of Gram-negative bacteriuria. The presence of intracellular Gram-negative diplococci on the smear correlates with infection with *N. gonorrhoeae*. The presence of only WBC on a urethral smear indicates the presence of non-gonorrhoeal urethritis. *C. trachomatis* is isolated in approximately two-thirds of these patients (2,6) (LE: 3).

Ejaculate analysis according to WHO criteria including leukocyte analysis indicates persistent inflammatory activity. In many cases, transient decreased sperm counts and forward motility can be found. Azosperma due to complete obstruction of both epididymides is a rare complication (8). If mumps orchitis is suspected, a history of parotitis and evidence of IgM antibodies in the serum supports the diagnosis. In about 20% of mumps orchitis cases, the disease occurs bilaterally in post-pubertal men with a risk of testicular
atrophy and azoospermia (3) (LE: 3).

11.6.1 Differential diagnosis
It is imperative for the physician to differentiate between epididymitis and spermatic cord torsion as soon as possible using all available information, including the age of the patient, history of urethritis, clinical evaluation and Doppler (duplex) scanning of testicular blood flow.

11.7 Treatment
Only a few studies have measured the penetration of antimicrobial agents into the epididymis and testes in humans. Of these, the fluoroquinolones have shown favourable properties (9) (LE: 2a).

Antimicrobials should be selected on the empirical basis that in young, sexually active men, C. trachomatis is usually causative, and that in older men, with BPH or other micturition disturbances, the most common uropathogens are involved. Studies that have compared microbiological results from puncture of the epididymis and from urethral swabs as well as urine have shown very good correlation. Therefore, before antimicrobial therapy, a urethral swab and MSU should be obtained for microbiological investigation (GR: C).

Again, fluoroquinolones, preferably those with activity against C. trachomatis (e.g. ofloxacin and levofloxacin), should be the drugs of first choice, because of their broad antibacterial spectra and their favourable penetration into the tissues of the urogenital tract. If C. trachomatis has been detected as an aetiological agent, treatment could also be continued with doxycycline, 200 mg/day, for a total period of at least 2 weeks. Macrolides may be used as alternative agents (GR: C).

Supportive therapy includes bed rest, up-positioning of the testes and antiphlogistic therapy. In young men, epididymitis can lead to permanent occlusion of the epididymal ducts and thus to infertility, therefore, one should consider antiphlogistic therapy with methylprednisolone, 40 mg/day, and reduce the dose by half every second day (GR: C).

In case of C. trachomatis epididymitis, the sexual partner should also be treated (GR: C). If uropathogens are found as causative agents, a thorough search for micturition disturbances should be carried out to prevent relapse (GR: C). Abscess-forming epididymitis or orchitis also needs surgical treatment. Chronic epididymitis can sometimes be the first clinical manifestation of urogenital tuberculosis.

12. FOURNIER’S GANCRENE

12.1 Summary of recommendations
1. Full, repeated surgical debridement should commence within 24 h of presentation (LE: 3; GR: B).
2. Treatment with broad-spectrum antibiotics should be started on presentation, with subsequently refinement according to culture and clinical response (LE: 3; GR: B).
3. Adjunctive treatment such as pooled immunoglobulin and hyperbaric oxygen are not recommended, except in the context of clinical trials (LE: 3; GR: C).

12.2 Background
Fournier’s gangrene is an aggressive and frequently fatal polymicrobial soft tissue infection of the perineum, peri-anal region, and external genitalia. It is an anatomical sub-category of necrotising fasciitis with which it shares a common aetiology and management pathway. Evidence regarding investigation and treatment is predominantly from case series and expert opinion (LE: 3/4).

12.3 Clinical presentation
Fournier's gangrene remains rare but its incidence is increasing with an ageing population and higher prevalence of diabetes, and emergence of multi-resistant pathogens. Typically there is painful swelling of the scrotum or perineum with severe sepsis. Examination shows a small necrotic areas of skin with surrounding erythema and oedema. Crepitus on palpation and a foul-smelling exudate occurs with more advanced disease. Risk factors include immuno-compromised patients, most commonly diabetes or malnutrition, or a recent history of catheterisation, instrumentation or perineal surgery. In up to 40% of cases, the onset is more insidious with undiagnosed pain often resulting in delayed treatment. A high index of suspicion and careful examination, particularly of obese patients, is required.

12.4 Microbiology
Fournier's gangrene is typically a type 1 necrotising fasciitis that is polymicrobial in origin, including S. aureus, Streptococcus sp., Klebsiella sp., E. coli and anaerobs; involvement of Clostridium sp. is now less common. These organisms secrete endotoxins causing tissue necrosis and severe cardiovascular impairment. Subsequent inflammatory reaction by the host contributes to multi-organ failure and death if untreated.

12.5 Management
The degree of internal necrosis is usually vastly greater than suggested by external signs, and consequently, adequate, repeated surgical debridement is necessary to save the patient's life (LE: 3; GR: B). Disease specific severity scoring systems do not appear superior to generic critical illness scores and are therefore not recommended for routine use (LE: 3;GR: C). Computed tomography or MRI can help define para-rectal involvement, suggesting the need for colostomy (LE: 3, GR: C). Consensus from case series suggests that surgical debridement should be early (< 24 h) and complete, because delayed and/or inadequate surgery results in higher mortality (LE: 3; GR: B). Concurrent parenteral antibiotic treatment should be given that covers all causative organisms and can penetrate inflammatory tissue (LE: 3, GR: B). This can then be refined following surgical cultures. The benefit of pooled immunoglobulin therapy and hyperbaric oxygen remains uncertain and should not be used routinely (LE:3, GR: C). With aggressive early surgical and medical management, survival rates are > 70% depending upon patient group and availability of critical care (LE: 3). Following resolution, reconstruction using skin grafts is required.

13.  SEXUALLY TRANSMITTED INFECTIONS

The classical bacteria that cause venereal diseases, e.g. gonorrhoea, syphilis, chancroid and inguinal granuloma, only account for a small proportion of all known sexually transmitted deceases (STDs) today. Other bacteria and viruses as well as yeasts, protozoa and epizoa must also be regarded as causative organisms of STD. Taken together, all STDs are caused by > 30 relevant pathogens. However, not all pathogens that can be sexually transmitted manifest genital diseases, and not all genital infections are exclusively sexually transmitted. At present, the reader is refered to the 2010 CDC STD Treatment Guidelines (1).

The human immunodeficiency virus (HIV) causes a disease of the immune system leading to a vast panorama of complications and complex medical conditions also called acquired immunodeficiency...

14. SPECIFIC INFECTIONS

Urogenital tuberculosis and bilharziasis are two infections that may affect the urogenital tract. Although not endemic in Europe, cases of urogenital tuberculosis are occasionally diagnosed in all communities. In a world of globalisation, travellers are regularly confronted with situations in which they may be infected. Guidelines on the diagnosis and management of these two infections have been published elsewhere. Following the abstract printed here, there is a direct link to these published guidelines, which can be consulted for free.

14.1 Urogenital tuberculosis
Nearly one third of the world’s population is estimated to be infected with M. tuberculosis. Moreover, tuberculosis is the most common opportunistic infection in AIDS patients. Urogenital tuberculosis is not very common but it is considered a severe form of extra-pulmonary tuberculosis. The diagnosis of urogenital tuberculosis is made based on culture studies by isolation of the causative organism; however, biopsy material on conventional solid media may occasionally be required. Drugs are the first-line therapy in urogenital tuberculosis. Treatment regimens of 6 months are effective in most patients. Although chemotherapy is the mainstay of treatment, surgery in the form of ablation or reconstruction may be unavoidable. Both radical and reconstructive surgery should be carried out in the first 2 months of intensive chemotherapy.

14.1.1 Reference

14.2 Urogenital schistosomiasis
More than 100 million people worldwide are affected by bilharziasis, which is caused by Schistosoma haematobium. For travellers, precautions are most important. For the population in endemic areas, an integrated approach including health education is necessary. Effective pharmacological treatment is available.

14.2.1 Reference

15. PERIOPERATIVE ANTIBACTERIAL PROPHYLAXIS IN UROLOGY

15.1 Summary and recommendations
The aim of antimicrobial prophylaxis in urological surgery is to prevent infective complications that result from diagnostic and therapeutic procedures at the time of surgery and in the immediate post-operative period. However, evidence for the best choice of antibiotics and prophylactic regimens is limited (Table 15.1).

Before surgery, it is essential to categorise the patients in relation to (1):
- general health status according to American Society of Anesthesiology (ASA) score P1-P5;
- presence of general risk factors such as older age, diabetes mellitus, impaired immune system, malnutrition, extreme weight;
- presence of specific endogenous or exogenous risk factors such as a history of UTI or urogenital...
infection, indwelling catheters, bacterial burden, previous instrumentation, genetic factors;

- type of surgery and surgical field contamination burden;
- expected level of surgical invasiveness, duration and technical aspects.

Only transrectal core prostate biopsy (LE: 1b, GR: A) and TURP (LE: 1a, GR: A) are well documented. There is no evidence for any benefits of antibiotic prophylaxis in standard non-complicated endoscopic procedures and shockwave lithotripsy (SWL), although it is recommended in complicated procedures and patients with identified risk factors.

For open and laparoscopic surgery, the same rules as in abdominal and gynaecological surgery can be applied. No antibiotic prophylaxis is recommended for clean operations, whereas a single or 1-day dose is recommended in clean-contaminated. The approach in contaminated operations varies with the type of procedure, the level of surgical site contamination and level of difficulty. Opening of the urinary tract is considered as clean-contaminated surgery.

A single dose or a short course of antimicrobials can be given parenterally or orally. The administration route depends on the type of intervention and patient characteristics. Oral administration requires drugs that have good bioavailability. In a case of continuous close urinary drainage, prolongation of perioperative antibiotic prophylaxis is not recommended.

Many antibiotics are suitable for perioperative antibacterial prophylaxis, e.g. co-trimoxazole, second-generation cephalosporins, fluoroquinolones, aminopenicillins plus a beta-lactam inhibitor, and aminoglycosides. Broader-spectrum antibiotics including fluoroquinolones should be used cautiously and reserved for treatment. This applies also to the use of vancomycin.

The use of antimicrobials should be based on knowledge of the local pathogen profile and antibiotic susceptibility pattern. Best practice includes surveillance and an audit of infectious complications.

15.2 Introduction

Antibiotic prophylaxis in urology has been controversial for many years. Most studies in the past have been poorly designed and lacked statistical power. There has been inconsistency concerning definitions and assessment of risk factors. Urological practice has changed particularly in the last decade and older studies are no longer relevant. Several surveys among urologists in Europe have revealed wide differences in regimens and choice of antibiotics for prophylaxis. Clearly, there is a need for evidence-based guidelines (2-6).

The present section aims to clarify the current state of knowledge and to propose practical recommendations based on clinical studies, expert opinion and professional consensus. The section also considers the recommendations of societies, such as the Paul Ehrlich Society for Chemotherapy, the corresponding working groups of the German Society of Urology (7), French Association of Urology (8) and of an international consensus working group (1).

One systematic review of antibiotic prophylaxis in urological surgery has been published (9). The results of the review strengthen the underlying documentation for the present recommendations.

A recent pan-European survey was carried out by the EAU Section for Infection in Urology (ESIU) in a large number of European countries, including > 200 urological services or units. The survey found that ≥10-12% of patients had a healthcare-associated UTI (10). Moreover, a review of antibiotic prophylaxis praxis showed large discrepancies in the use of antibiotic prophylaxis in all type of procedures and between countries, and low compliance to the guidelines (11). The surveys illustrate the need for a stringent antibiotic policy throughout Europe, and that recommendations for antibiotic prophylaxis should be included in the general antibiotic policy of each hospital.

The microbial development of resistance presents a challenge to the urological community for both treatment and prophylaxis. It is essential that the urologist is aware of the microbial pattern and resistance profile in his/her community and can assess the risk of each individual patient of harbouring resistant strains (see Section 1.2).

15.3 Goals of perioperative antibacterial prophylaxis

Antibiotic prophylaxis and therapy are two different issues. Antibiotic prophylaxis aims to prevent healthcare-associated infections that result from diagnostic and therapeutic procedures. Antibiotic prophylaxis is only one of several measures to prevent infections and can never compensate for poor hygiene and operative technique. In contrast, antibiotic therapy is the treatment of a clinically suspected or microbiologically proven infection.

There is a dilemma regarding the definition of infections. The US CDC have presented definitions that are currently the most comprehensive, and are recommended for the evaluation of infectious complications (12). These definitions have also been used in the recent pan-European study on nosocomial UTI (10). Revision of definitions and recommendations are on-going in some countries (13). Table 15.2 illustrates the different types of infectious complications encountered in urological surgery.

</table>
Surgical site infections are seen after open surgery and to some extent after laparoscopic surgery. Febrile and complicated UTIs are mainly complications of endoscopic surgery and the use of indwelling catheters and stents. They can also occur following open surgery of the urinary tract. Sepsis can be seen with all types of procedures.

The endpoints of perioperative prophylaxis in urology are debatable. It is generally agreed that its main aim is to prevent symptomatic, febrile urogenital infections such as acute pyelonephritis, prostatitis, epididymitis and urosepsis, as well as serious wound infections directly related to surgery (Table 15.2). This might be extended to asymptomatic bacteriuria and even minor wound infections, which could easily be treated on an outpatient basis. In some circumstances, even minor wound infections can have serious consequences, as in implant surgery. However, asymptomatic bacteriuria after TURP or other endourological procedures can disappear spontaneously and is usually of no clinical significance. Another question is whether perioperative prophylaxis should also be concerned with the prevention of non-urological infections, e.g. endocarditis and postoperative pneumonia. Perioperative antibacterial prophylaxis in urology must go beyond the traditional aim of prophylaxis in surgery, which is the prevention of wound infections.

15.4 Risk factors

Risk factors (Table 15.3 and 2.1) are underestimated in most trials. However, they are important in the preoperative assessment of the patient. They are related to:

- general health of the patient as defined by ASA score P1-P5;
- presence of general risk factors such as older age, diabetes mellitus, impaired immune system, malnutrition, extreme weight;
- presence of specific endogenous or exogenous risk factors such as a history of UTI or urogenital infection, indwelling catheters, bacterial burden, previous instrumentation, genetic factors;
- type of surgery and surgical field contamination;
- expected level of surgical invasiveness, duration and technical aspects.

The traditional classification of surgical procedures according to Cruse and Foord (14) into clean, clean-contaminated, contaminated, and infected/dirty operations applies to open surgery but not to endourological interventions. It is still debated whether opening of the urinary tract (i.e. bladder surgery, radical prostatectomy, or surgery of the renal pelvis and ureter) should be classified as clean or clean-contaminated surgery in cases of negative urine culture. The same applies to endoscopic and transurethral surgery. However, members of the EAU Expert Group consider these procedures as clean-contaminated because urine culture is not always a predictor of bacterial presence, and the lower genitourinary tract is colonised by microflora, even in the presence of sterile urine (6,15,16).

</tr>
</tbody>
</table>

The pan-European study on nosocomial UTI (10) has identified the three most important risk factors for infectious complications as:

- an indwelling catheter;
- previous urogenital infection;
- long preoperative hospital stay.

The risk of infection varies with the type of intervention. The wide spectrum of interventions further complicates the provision of clear-cut recommendations. Furthermore, the bacterial load, the duration and difficulty of the operation, the surgeon's skill, and perioperative bleeding may also influence the risk of infection (6).

15.5 Principles of antibiotic prophylaxis

Antibiotic prophylaxis aims at protecting the patient but not at the expense of promoting resistance. However,
there is good evidence that intelligent use of prophylaxis can lower the overall consumption of antibiotics (16,17). It is essential to individualise the choice of antibiotic prophylaxis according to each patient’s cumulative risk factors (18). Urine culture prior to surgery is strongly recommended. Antibiotics cannot replace other basic measures to reduce infection (19-21).

Unfortunately, the benefit of antibiotic prophylaxis for most modern urological procedures has not yet been established by well-designed interventional studies.

15.5.1 **Timing**

There is a given time-frame during which antibiotic prophylaxis should be administered. Although the following guidelines are based on research into skin wounds and clean-contaminated and contaminated bowel surgery, there is good reason to believe that the same findings apply to urological surgery. The optimal time for antibiotic prophylaxis is 1-2 h before instrumentation. Some studies on bowel surgery indicate similar results up to 3 h after the start of an intervention (22-24).

For practical purposes, oral antibiotic prophylaxis should be given approximately 1 h before the intervention. Intravenous antibiotic prophylaxis should be given at the induction of anaesthesia. These timings allow antibiotic prophylaxis to reach a peak concentration at the time of highest risk during the procedure, and an effective concentration shortly afterwards (25). It is worth noting that a bloodstream infection can develop in less than an hour (22).

15.5.2 **Route of administration**

Oral administration is as effective as the intravenous route for antibiotics with sufficient bioavailability. This is recommended for most interventions when the patient can easily take the drug 1 h before intervention. In other cases, intravenous administration is recommended. Local irrigation of the operating field with antibiotics is not recommended.

15.5.3 **Duration of the regimen**

For most procedures, duration of antibiotic prophylaxis has not yet been adequately addressed and rarely can a defined regimen be recommended. In principle, the duration of perioperative prophylaxis should be minimised; ideally to a single preoperative antibiotic dose. Perioperative prophylaxis should be prolonged only where there are significant risk factors (see Section 15.4).

15.5.4 **Choice of antibiotics**

No clear-cut recommendations can be given, as there are considerable variations in Europe regarding both bacterial spectra and susceptibility to different antibiotics. Antimicrobial resistance is usually higher in Mediterranean compared with Northern European countries; resistance is correlated with an up to fourfold difference in sales of antibiotics (26). Thus, knowledge of the local pathogen profile, susceptibility and virulence is mandatory in establishing local antibiotic guidelines. It is also essential to define the predominant pathogens for each type of procedure. When choosing an antimicrobial agent, it is necessary to consider the procedure-specific risk factors, contamination load, target organ, and the role of local inflammation.

In general, many antibiotics are suitable for perioperative antibacterial prophylaxis, e.g. co-trimoxazole, second-generation cephalosporins, aminopenicillins plus a BLI, aminoglycosides and fluoroquinolones. Broader-spectrum antibiotics should be used sparingly and reserved for treatment. Fluoroquinolones should be avoided as far as possible for prophylaxis. This applies also to the use of vancomycin.

15.6 **Prophylactic regimens in defined procedures**

All procedures are not alike. There is a large variation in invasiveness and risk for identical interventions. The empirical relationship between the level of invasiveness and risk for infective complications is illustrated in Figure 15.1. Moreover, a tentative classification of the urological procedures in relation to the surgical field contamination level is given in Table 15.5.a and 15.5.b.
The EAU/ESIU working group has suggested a distribution of the different common diagnostic and therapeutic urological procedures in relation to the categories of surgical site contamination after adaptation to the urological context (14,27). The recommendations for antibiotic prophylaxis in standard urological surgery are summarised in Table 15.4a and 15.4b (28,29).

15.6.1 Diagnostic procedures
Antimicrobial prophylaxis in core biopsy of the prostate is generally recommended (GR: A). However, the choice of regimens remains debatable. Most regimens used are effective, and recent studies have suggested that 1-day and even single doses are sufficient in low-risk patients (30-45) (LE: 1b, GR: A). The increase in fluoroquinolones resistance in the faecal flora has raised the question of appropriateness of the current recommendations (46,47). No clear-cut alternative is evidence-based. Each urologist must weigh the need for a prostate biopsy in relation to the risk, assess the individual risks factors including the risk of harbouring a resistant bacteria (i.e. ESBL) and consider the need for a rectal swab before the instrumentation.

The frequency of infectious complications after cystoscopy, urodynamic studies and diagnostic simple ureteroscopy is low. The use of antibiotic prophylaxis is still debated and the results are controversial. In view of the very large number of cystoscopic examinations and the potential adverse effect on bacterial sensitivity, antibiotic prophylaxis is not recommended in standard cases. However, bacteriuria, indwelling catheters, and a history of urogenital infection are risk factors that must be considered (48-62) (LE: 1b, GR: A).

15.6.2 Endourological treatment procedures (urinary tract entered)
There is little evidence for any benefit of antibiotic prophylaxis in TURB. However, antibiotic prophylaxis should be considered in patients with large tumours with a prolonged resection time, large necrotic tumours, and with risk factors (49,63,64) (LE: 2b, GR: C).

Transurethral resection of the prostate is the best-studied urological intervention. A meta-analysis of 32 prospective, randomised and controlled studies, including > 4,000 patients, showed a benefit of antibiotic prophylaxis with a relative risk reduction of 65% and 77% for bacteriuria and septicaemia, respectively (16,65-67) (LE: 1a, GR: A). There is a difference between smaller resections in healthy patients and large resections in at-risk patients (Figure 15.1).

There have been few studies that have defined the risk of infection following ureteroscopy and percutaneous stone removal, and no clear-cut evidence exists (68). It is reasonable, however, to distinguish low-risk procedures, such as simple diagnostic and distal stone treatment, from higher-risk procedures, such as treatment of proximal impacted stones and intrarenal interventions (Figure 15.1) (5). Other risk factors (i.e. size, length, bleeding, and surgeon’s experience) also need to be considered in the choice of regimen (69-76) (LE: 2b, GR: B).

Shockwave lithotripsy is one of the most commonly performed procedures in urology. No standard prophylaxis is recommended. However, prophylaxis is recommended in cases of internal stent and treatment, due to the increased bacterial burden (e.g. indwelling catheter, nephrostomy tube, or infectious stones) (77-86) (LE: 1a-1b, GR: A).

Most antibiotic groups have been evaluated, such as fluoroquinolones, BLIs, including cephalosporins, and co-trimoxazole, but comparative studies are limited.
15.6.3 Laparoscopic surgery
There has been a lack of sufficiently powered studies in laparoscopic urological surgery. However, it seems reasonable to manage laparoscopic surgical procedures in the same manner as the corresponding open procedures (LE: 4, GR: C).

15.6.4 Open or laparoscopic urological operations without opening of the urinary tract (clean procedures)
No standard antibiotic prophylaxis is recommended in clean operations (87-94) (LE: 3, GR: C).

15.6.5 Open or laparoscopic urological operations with open urinary tract (clean-contaminated procedures)
In cases of opening the urinary tract, a single perioperative parenteral dose of antibiotics is recommended (LE: 3, GR: C). This is valuable for standard procedures such as total (radical) prostatectomy (92-95). In open enucleation of prostatic adenoma, the risk of postoperative infection is particularly high (96) (LE: 2b, GR: B).

15.6.6 Open urological operations with bowel segment (clean-contaminated or contaminated procedures)
Antibiotic prophylaxis is recommended, as for clean-contaminated operations in general surgery. Single or 1-day dosage is recommended, although prolonged operation and other morbidity risk factors might support the use of a prolonged regimen, which should be < 72 h. The choice of antibiotic should focus on aerobic and anaerobic pathogens. Evidence is based on colorectal surgery (LE: 1a, GR: A), but experience is limited as for specific urological interventions (97-100) (LE: 2a, GR: B).

15.6.7 Postoperative drainage of the urinary tract
When continuous urinary drainage is left in place after surgery, prolongation of perioperative antibacterial prophylaxis is not recommended, unless a complicated infection that requires treatment is suspected. Asymptomatic bacteriuria (bacterial colonisation) should only to be treated before surgery or after removal of the drainage tube (LE: 3, GR: B).

15.6.8 Implantation of prosthetic devices
When infectious complications occur in implant surgery, they are usually problematic and often result in removal of the prosthetic device. Diabetes mellitus is considered a specific risk factor for infection. Skin-related staphylococci are responsible for most infections. The antibiotics used must be chosen to target these strains (101-104) (LE: 2a, GR: B).

Table 15.4a: Surgical Wound classes modified from (13) and adapted to urological surgery. Tentative classification of urological procedures in relation to the different levels of surgical field contamination. The risk of wound infection or SSI expressed in per cent (within brackets in left column) is that of classical wound infections without antibiotic prophylaxis and not bacteriuria or clinical UTI in urological surgery (Modified from Urogenital infections, EAU/ICUD, 2010, p 674-75). In this table some examples of open and laparoscopic procedures are given and the ABp basic principle.

## 16. APPENDICES

### 16.1 Criteria for the diagnosis of UTI, as modified according to IDSA/European Society of Clinical Microbiology and Infectious Diseases guidelines (1-3)

<table>
<thead>
<tr>
<th>Category</th>
<th>Description</th>
<th>Clinical features</th>
<th>Laboratory investigations</th>
</tr>
</thead>
</table>
| 1        | Acute uncomplicated UTI in women; acute uncomplicated cystitis in women | Dysuria, urgency, frequency, suprapubic pain, no urinary symptoms in 4 weeks before this episode | > 10 WBC/mm³  
> 10³ cfu/mL* |
| 2        | Acute uncomplicated pyelonephritis | Fever, chills, flank pain; other diagnoses excluded; no history or clinical evidence of urological abnormalities (ultrasonography, radiography) | > 10 WBC/mm³  
> 10⁴ cfu/mL* |
| 3        | Complicated UTI | Any combination of symptoms from categories 1 and 2 above; one or more factors associated with a complicated UTI (see text) | > 10 WBC/mm³  
> 10⁵ cfu/mL* in women  
> 10⁴ cfu/mL* in men, or in straight catheter urine in women |
| 4        | Asymptomatic bacteriuria | No urinary symptoms | > 10 WBC/mm³  
> 10⁵ cfu/mL* in two consecutive MSU cultures  
> 24 h apart |
| 5        | Recurrent UTI (antimicrobial prophylaxis) | At least three episodes of uncomplicated infection documented by culture in past 12 months: women only; no structural/functional abnormalities | < 10³ cfu/mL* |

All pyuria counts refer to unspun urine.

*Uropathogen in MSU culture.

16.4  CPSI

NIH-Chronic Prostatitis Symptom Index (NIH-CPSI)

Pain or Discomfort
1. In the last week, have you experienced any pain or discomfort in the following areas?
   a. Area between rectum and testicles (perineum)
      Yes □ 1  No □ 0
   b. Testicles
      □ 1  □ 0
   c. Tip of penis (not related to urination)
      □ 1  □ 0
   d. Below your waist, in your pubic or bladder area
      □ 1  □ 0

2. In the last week, have you experienced:
   a. Pain or burning during urination?
      Yes □ 1  No □ 0
   b. Pain or discomfort during or after sexual climax (ejaculation)?
      □ 1  □ 0

3. How often have you had pain or discomfort in any of these areas over the last week?
   □ 0 Never
   □ 1 Rarely
   □ 2 Sometimes
   □ 3 Often
   □ 4 Usually
   □ 5 Always

4. Which number best describes your AVERAGE pain or discomfort on the days that you had it, over the last week?
   □ 0 □ 1 □ 2 □ 3 □ 4 □ 5 □ 6 □ 7 □ 8 □ 9 □ 10
   NO = PAIN AS BAD
   AS YOU CAN IMAGINE

Urination
5. How often have you had a sensation of not emptying your bladder completely after you finished urinating over the last week?
   □ 0 Not at all
   □ 1 Less than 1 time in 5
   □ 2 Less than half the time
   □ 3 About half the time
   □ 4 More than half the time
   □ 5 Almost always

6. How often have you had to urinate again less than two hours after you finished urinating, over the last week?
   □ 0 Not at all
   □ 1 Less than 1 time in 5
   □ 2 Less than half the time
   □ 3 About half the time
   □ 4 More than half the time
   □ 5 Almost always

Impact of Symptoms
7. How much have your symptoms kept you from doing the kinds of things you would usually do over the last week?
   □ 0 None
   □ 1 Only a little
   □ 2 Some
   □ 3 A lot

8. How much did you think about your symptoms, over the last week?
   □ 0 None
   □ 1 Only a little
   □ 2 Some
   □ 3 A lot

Quality of life
9. If you were to spend the rest of your life with your symptoms, just the way they have been during the last week, how would you feel about that?
   □ 0 Delighted
   □ 1 Pleased
   □ 2 Mostly satisfied
   □ 3 Mixed (about equally satisfied and dissatisfied)
   □ 4 Mostly dissatisfied
   □ 5 Unhappy
   □ 6 Terrible

96  UROLOGICAL INFECTIONS - LIMITED UPDATE MARCH 2013
16.5 Meares & Stamey localisation technique*

**MEARES AND STAMEY LOCALIZATION TECHNIQUE**

1. Approximately 30 minutes before taking the specimen, the patient should drink 400ml of liquid (two glasses). The test starts when the patient wants to void.
2. The lids of the sterile specimen containers, which are marked VB1, VB2, EPS and VB3, should be removed. Place the uncovered specimen containers on a flat surface and maintain sterility.
3. Hands are washed.
4. Expose the penis and retract the foreskin so that the glans is exposed. The foreskin should be retracted throughout.
5. Cleanse the glans with a soap solution, remove the soap with sterile gauze or cotton and dry the glans.
6. Urinate 10-15ml into the first container marked VB1.
7. Urinate 100-200ml into the toilet bowl or vessel and without interrupting the urine stream, urinate 10-15ml into the second container marked VB2.
8. The patient bends forward and holds the sterile specimen container (EPS) to catch the prostatic secretion.
9. The physician massages the prostate until several drops of prostatic secretion (EPS) are obtained.
10. If no EPS can be collected during massage, a drop may be present at the office of the urethra and this drop should be taken with a 10μl calibrated loop and cultured.
11. Immediately after prostatic massage, the patient urinates 10-15ml of urine into the container marked VB3.

</tbody>
</table>
16.6.1 Penicillins
Penicillin G and the oral penicillins, penicillin V, propicillin and azidocillin, have a high intrinsic activity against streptococci and pneumococci. However, the resistance rate of pneumococci may vary considerably between countries. In Germany, penicillin resistance in pneumococci is still < 1%. Because of their narrow spectrum of activity, these penicillins do not have any role in the treatment of urogenital infections.

16.6.1.1 Aminopenicillins
Aminopenicillins, e.g. ampicillin and amoxycillin, have a broader spectrum of activity. Apart from streptococci and pneumococci, they cover enterococci, Haemophilus influenzae, Haemophilus parainfluenzae, Listeria sp., E. coli, Pr. mirabilis, and Salmonella and Shigella sp. However, resistance may occur.

Aminopenicillins are sensitive to β-lactamases. They are therefore not sufficiently active against certain species, such as staphylococci, Moraxella catarrhalis, Bacteroides fragilis and many enterobacteria. This gap in the spectrum of activity can be closed by the use of a BLI (clavulanic acid, or sulbactam). Amoxycillin/clavulanic acid and ampicillin/sulbactam are available on the market as fixed combinations. Indications for aminopenicillins and their combinations with a BLI are mild respiratory tract infections, UTIs, as well as infections of the skin and soft tissues.

16.6.1.2 Acylaminopenicillins
The acylaminopenicillins include apalcillin, azlocillin, mezlocillin and piperacillin. They are characterised by their high activity against enterococci, enterobacteria and Pseudomonas (weaker activity of mezlocillin). Acylaminopenicillins are hydrolyzed by β-lactamases and are therefore active only against β-lactamase-producing strains of staphylococci, B. fragilis, and if used in combination with a BLI, some of the enterobacteria. The acylaminopenicillin/BLI combination provides a broad spectrum of activity and may be used for a large number of indications, including complicated UTIs and urosepsis. A selection of free combinations with sulbactam is available, or there is the fixed combination of tazobactam and piperacillin, which has the advantages of being easy to use and a well-documented database drawn from qualified clinical studies.

16.6.1.3 Isoxazolylpenicillins
Isoxazolylpenicillins are available as parenteral drugs with oxacillin and flucloxacillin, and have a narrow

1Classification according to the Paul Ehrlich Society for Chemotherapy (1-3).
2Only in adults, except pregnant and lactating women.
3Only in acute, uncomplicated cystitis as a single dose.
4Contraindicated in renal failure and in newborns.
5In cases of resistance, the pathogen is most likely to be a β-lactamase producer.
6BLIs can only be used in combination with β-lactam antibiotics.
7In solution, storage instability.
spectrum of activity. Their indications are limited to infections caused by S. aureus. Due to their suboptimal pharmacokinetic parameters, isoxazolylpenicillins are preferably used in milder infections of the skin and soft tissues, and of the ear, nose and throat area. They play no role in the treatment of UTIs, but may be used for staphylococcal abscesses in the genital area.

16.6.2 Parenteral cephalosporins
According to the Paul Ehrlich Society for Chemotherapy (1), the parenteral cephalosporins have been classified into five groups, according to their spectrum of activity (Table 16.7.2).

16.6.2.1 Group 1 cephalosporins
Group 1 cephalosporins (cefazolin and cefazedone) are very active against streptococci and staphylococci (including penicillin-G-resistant strains). They have only weak activity against Gram-negative microorganisms. Like all cephalosporins, cefazolin is not active against enterococci and MRSA and methicillin-resistant coagulase-negative staphylococci (MRSE).

16.6.2.2 Group 2 cephalosporins
Compared with Group 1 cephalosporins, Group 2 cephalosporins, e.g. cefuroxime, cefotiam and cefamandole, exhibit markedly improved activity against Gram-negative pathogens and maintain high activity against staphylococci.

16.6.2.3 Group 3a cephalosporins
Group 3a cephalosporins have high activity against Gram-negative bacteria and less activity against staphylococci. They differ mainly in their pharmacokinetic characteristics.

16.6.2.4 Group 3b cephalosporins
Group 3b cephalosporins, e.g. ceftazidime and cefoperazone, have added high anti-pseudomonal activity. However, the activity of cefoperazone against P. aeruginosa is markedly inferior to that of the other substances in this group.

16.6.2.5 Group 4 cephalosporins
Group 4 cephalosporins, e.g. cefepime and cefpirome, have a comparable activity against Gram-negative bacteria, but are more stable against extended-spectrum β-lactamases, and a better activity against Gram-positive bacteria.

16.6.2.6 Group 5 cephalosporins
The Group 5 cephalosporins are characterised by their anti-anaerobic activity. These cephalosporins have superior activity against Gram-negative bacteria compared with Group 1 and 2 cephalosporins, but most of them are weaker than Group 3 drugs. At present, cefoxitin is the only drug of that group available on the market in some countries.
Table 16.6.2: Classification of parenteral cephalosporins (2)

• Unstable against β-lactamases of Gram-negative bacteria |
| Group 2 (2nd generation) | Cefuroxime  Cefotiam  Cefamandole | • Activity against Gram-positive bacteria good, but weaker than Group 1  
• Activity against Gram-negative bacteria superior to that of Group 1  
• Stable against staphylococcal penicillinases  
• Limited stability against β-lactamases of Gram-negative bacteria |
| Group 3a (3rd generation) | Cefotaxime  Ceftriaxone  Cefitoxime  Cefmenoxime  Cefodizime | • Activity against Gram-negative bacteria clearly superior to that of Groups 1 and 2  
• Stable against numerous β-lactamases of Gram-negative bacteria  
• Microbiologically less active against staphylococci |
| Group 3b (3rd generation) | Ceftazidime  Cefoperazone | • Spectrum of antibacterial activity similar to that of Group 3a  
• Additional activity against P. aeruginosa |
| Group 4 | Cefepime  Cefpirome | • Spectrum of antibacterial activity similar to that of Group 3a  
• Additional activity against P. aeruginosa  
• Higher stability against beta-lactamases than group 3b  
• With anti-anaerobic activity  
• Superior activity against Gram-negative bacteria than Group 1 and 2  
• Weaker than Group 3 |
| Group 5 | Cefoxitin | |

16.6.3 Oral cephalosporins

Oral cephalosporins are classified into three groups, based on their spectrum of activity, according to the recommendations of the Paul Ehrlich Society for Chemotherapy (1) (Table 16.7.3).

Table 16.7.3: Classification of oral cephalosporins (1)

<table>
<thead>
<tr>
<th>Oral cephalosporins</th>
<th>Drug names</th>
</tr>
</thead>
<tbody>
<tr>
<td>Group 1</td>

</tr>
<tr>
<td>Group 3</td>
<td>Cefpodoxime proxetile  Cefetamet pivoxile  Ceftibuten  Cefixime</td>
</tr>
</tbody>
</table>

16.6.3.1 Group 1 oral cephalosporins

Group 1 oral cephalosporins include cefalexin, cefadroxil and cefaclor. They are mainly active against Gram-positive cocci with limited activity against *H. influenzae* (cefACLor). Their main indications are skin and soft tissue infections and, with limitations, respiratory tract infections. Their activity against enterobacteria is limited,
therefore, they can only be recommended for the treatment or prophylaxis of uncomplicated UTIs in children or pregnant women, for whom the use of other antibiotics is limited.

16.6.3.2 Group 2 oral cephalosporins
The activity of cefprozil against *S. aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *H. influenzae* and *Mor. catarrhalis* is somewhat higher than that of cefaclor. However, cefprozil is less active than cefaclor against *E. coli*, *Klebsiella pneumoniae* and *Pr. mirabilis*.

Loracarbef is structurally close to cefaclor. In contrast to cefaclor, it is stable in solution, has better pharmacokinetics and a broader antibacterial spectrum. However, its activity against staphylococci is lower than that of cefaclor. The main indications are respiratory tract, skin and soft-tissue infections and uncomplicated UTIs.

Cefuroxime axetile has a higher β-lactamase stability and thus a broader spectrum than others in this group. It can be used mainly for bacterial infections of the upper (including otitis media) and lower respiratory tract, for skin and soft-tissue infections, and UTIs.

16.6.3.3 Group 3 oral cephalosporins
Group 3 oral cephalosporins have a higher activity and a broader spectrum against enterobacteria than group 2 cephalosporins. In contrast, their activity against Gram-positive bacteria is lower. Against staphylococci, the activity of cefpodoxime proxetil is intermediate, whereas cefetamet pivoxil, ceftibuten and cefixime are inactive.

The main indications for the oral cephalosporins of group 3 are complicated infections of the respiratory tract (provided that staphylococci can be excluded) and infections due to enterobacteria, e.g. UTIs or infections in immunocompromised patients. Group 3 oral cephalosporins are also suitable for oral switch therapy, i.e. when initial parenteral therapy (using a parenteral group 3a cephalosporin) needs to be continued orally. In addition, cefixime is licensed also for treatment of gonorrhoea.

16.6.4 Monobactams
Among the monobactams, only aztreonam is available. It is active only against Gram-negative aerobes. In this respect, its spectrum and activity are similar to those of the parenteral group 3b cephalosporins.

16.6.5 Carbapenems
Carbapenems are broad-spectrum antibiotics with good activity against Gram-positive and Gram-negative bacteria, including anaerobes. They are preferably used in the treatment of mixed infections and in the initial therapy of life-threatening diseases, including urosepsis. Imipenem/cilastatin, meropenem and doripenem are also active against *P. aeruginosa*. However, ertapenem is not active against *P. aeruginosa*. Ertapenem has a longer half-life than imipenem/cilastatin and meropenem, and is therefore, suitable for once-daily dosing.

16.6.6 Fluoroquinolones
Non-fluorinated quinolones are no longer recommended because of their poor antibacterial activity. According to the Paul Ehrlich Society for Chemotherapy, the fluoroquinolones are classified into four groups, based on their spectrum of activity, their pharmacokinetics and indications (Table 16.6.4).

Table 16.6.4: Classification of fluoroquinolones, as modified according to the Paul Ehrlich Society for Chemotherapy (3)

</tr>
</tbody>
</table>

* Listed according to increasing *in vitro* activity (minimum inhibitory concentration) against indicative pathogens.
** In France and other countries, pefloxacin is also available for systemic use.
*** Investigated in acute exacerbations of chronic bronchitis, UTIs, gonorrhoea and gastrointestinal infections.

#### 16.6.6.1 Group 1 fluoroquinolones

The indications for group 1 fluoroquinolones are limited to UTIs in some countries, e.g. Germany. In France and some other countries, pefloxacin is also used for systemic oral and parenteral use. Norfloxacin is not available as parenteral antibiotic.

#### 16.6.6.2 Group 2 fluoroquinolones

Group 2 fluoroquinolones includes fluoroquinolones for systemic use with a broad spectrum of indications. These include infections of the urinary tract, respiratory tract, skin and soft tissues, bones and joints, as well as systemic infections and even sepsis. Group 2 fluoroquinolones exhibit good activity against enterobacteria and *H. influenzae*, with less activity against staphylococci, pneumococci, enterococci and atypical pathogens, e.g. *Chlamydia, Legionella* and *Mycoplasma* sp. Their activity against *P. aeruginosa* varies, with ciprofloxacin being most active in vitro. In addition, ciprofloxacin, ofloxacin and fleroxacin are also available for parenteral use.

#### 16.6.6.3 Group 3 fluoroquinolones

The main difference in the spectra of activity of group 3 fluoroquinolones (levofloxacin) and group 4 fluoroquinolones (gatifloxacin and moxifloxacin) is that the former have a higher intrinsic activity against Gram-positive pathogens, such as staphylococci, streptococci, pneumococci and enterococci.

However, group 3 and group 4 fluoroquinolones have comparable activity against Gram-negative pathogens. In addition, they have improved activity against the so-called atypical pathogens, such as *Chlamydia, Mycoplasma* and *Legionella* sp. In addition, group 4 fluoroquinolones have improved anti-anaerobic activity.

The only group 3 fluoroquinolone available for parenteral use is levofloxacin; the left enantiomer of the ofloxacin racemate. The main indications for levofloxacin are respiratory tract infections, and, due to its high renal elimination rate, UTIs, as well as skin and soft-tissue infections.

Among group 4 fluoroquinolones, gatifloxacin (not on the market in Europe), moxifloxacin and trovafloxacin have been licensed. However, in June 1999, trovafloxacin was taken off the market because of severe side effects. Thus, to date, no parenteral fluoroquinolone of this group has been made available.

Apart from respiratory tract infections, these broad-spectrum fluoroquinolones are appropriate for treatment of skin, soft-tissue and intra-abdominal infections, and oral treatment of gynaecological infections. However, final judgement of their position in the treatment of these diseases is not yet possible. Gatifloxacin has the highest renal excretion (about 84%) after oral administration. It is therefore also the most suitable for the treatment of uncomplicated and complicated UTI. Urinary excretion of moxifloxacin after oral administration is only in the range of about 20%.

#### 16.6.7 Co-trimoxazole

The treatment of UTIs is the main indication for trimethoprim alone or in combination with a sulphonamide, e.g. sulphamethoxazole. Trimethoprim with or without sulphamethoxazole can also be used for the prophylaxis of recurrent cystitis. The resistance rate against *E. coli* can vary between countries. It is therefore not recommended for empirical therapy of acute uncomplicated cystitis or pyelonephritis, when the resistance rate in the area is > 10-20% (4). In complicated UTIs, co-trimoxazole should only be used in accordance with sensitivity testing. Trimethoprim, especially in combination with sulphamethoxazole, can lead to severe although rare adverse events, such as Lyell syndrome, Stevens-Johnson syndrome and pancytopenia.

#### 16.6.8 Fosfomycin

Fosfomycin is active against Gram-negative and Gram-positive bacteria. The sodium salt is only for parenteral use. Fosfomycin trometamol is licensed for single-dose (3 g) treatment of uncomplicated cystitis in women.
16.6.9 **Nitrofurantoin**

The antibacterial activity of nitrofurantoin is limited to the urinary tract because of its low serum concentrations. It is active against *E. coli*, *Citrobacter* and most strains of *Klebsiella* and *Enterobacter*, whereas *Providencia* and *Serratia* are mostly resistant. *Proteus, P. aeruginosa* and *Acinetobacter* are almost always resistant. It is active against Gram-positive cocci, e.g. enterococci and staphylococci.

It is suitable only for the treatment or prophylaxis of uncomplicated UTIs. Short-term therapy for this indication has not been proven in sufficiently large studies. Little development of resistance has been observed over many years. Treatment can lead to severe, though rare adverse events, such as chronic desquamative interstitial pneumonia with fibrosis.

16.6.10 **Macrolides**

Erythromycin is the only macrolide that is available for both oral and parenteral use. The newer macrolides, roxithromycin, clarithromycin and azithromycin, are better tolerated than erythromycin, but can only be administered orally. The macrolides have good activity against streptococci, pneumococci, *Bordetella pertussis*, and *Chlamydia, Mycoplasma* and *Legionella* sp. The macrolides are not active against Gram-negative rods, therefore, their use in the treatment of UTIs is limited to special indications, such as non-gonococcal urethritis due to *C. trachomatis*.

16.6.11 **Tetracyclines**

The resistance against doxycycline and tetracycline of pneumococci, streptococci, *H. influenzae* and *E. coli* shows marked regional differences. Tetracyclines are therefore only suitable for initial empirical therapy if the local resistance situation is sufficiently well known and justifies their use. As a result of their high activity against the so-called atypical pathogens (*Legionella, Chlamydia* and *Mycoplasma* sp.), they may be used as alternative antibiotics in infections caused by these microorganisms, e.g. in non-gonococcal urethritis due to *C. trachomatis*.

16.6.12 **Aminoglycosides**

Aminoglycosides are for parenteral use only. These drugs have a narrow therapeutic window. Their effective levels of activity are close to toxic borderline concentrations, making a strict therapeutic indication mandatory. With few exceptions (e.g. treatment of UTIs), aminoglycosides should only be used in combination with another appropriate antibiotic. Ideal partners are β-lactam antibiotics, because this combination has a marked synergistic effect against certain bacterial species. Streptomycin is one of the older aminoglycosides and is used only for the treatment of tuberculosis.

Newer aminoglycosides include netilmicin, gentamicin, tobramycin and amikacin. They have good activity against enterobacteria and *Pseudomonas* (especially tobramycin). Their activity against streptococci, anaerobes and *H. influenzae* is not satisfactory. Resistance data for tobramycin, gentamicin and netilmicin are almost identical, whereas the resistance situation is more favourable for amikacin against many enterobacteria.

16.6.13 **Glycopeptides**

The glycopeptides vancomycin and teicoplanin are active against Gram-positive pathogens, i.e. staphylococci (including oxacillin-resistant strains), streptococci, enterococci, *Clostridium difficile*, diphtheria bacteria and Gram-positive aerobes. They are inactive against Gram-negative pathogens. Their use is indicated:

- In infections caused by the above-mentioned pathogens in case of allergy against all other suitable antibiotics.
- In infections caused by ampicillin-resistant enterococci or oxacillin-resistant staphylococci, or multi-resistant corynebacteria.
- As an alternative, in oral form, to metronidazole for the treatment of pseudomembranous colitis. Due to the risk of selection of glycopeptide-resistant enterococci and staphylococci, the use of glycopeptides should be highly restricted. Similar to the aminoglycosides, glycopeptides have a narrow therapeutic window.

16.6.14 **Oxazolidinones**

The only substance of this group is linezolid, which can be administered parenterally and orally. It has good activity against Gram-positive cocci, such as staphylococci, including methicillin (oxacillin)-resistant strains, enterococci, including vancomycin-resistant strains, and streptococci.

16.7 Relevant bacteria for urological infections

Obligate intracellular bacteria
- Chlamydia
  - C. trachomatis

No cell wall
- Mycoplasma
  - M. hominis
  - M. genitalium
- Ureaplasma
  - U. urealyticum

Spirochetes
- Treponema
  - T. pallidum

Rods*
- Ziehl-Neelsen Positive
- Mycobacteria
  - M. tuberculosis
- Corynebacteria
  - C. urealyticum
  - Listeria
  - Bacilli

Gram-positive aerobic
- Enterobacteriaceae
  - Escherichia
  - Klebsiella
  - Citrobacter
  - Proteus
  - Serratia
  - Providencia
  - Enterobacter
  - Pantoea
  - Hafnia
  - Salmonella
  - Shigella

Non-Fermenter
- Pseudomonas
- Acinetobacter
- Xanthomonas
- Burgholderia

Parvobacteria
- Haemophilus
  - Gardnerella vaginalis

Gram-negative aerobic
- Neisseria
  - N. gonorrhoeae

Cocci*
- Streptococcus
  - α-haemolytic
    - S. viridans
  - β-haemolytic
    - S. pyogenes
      - group A
    - S. agalactiae
      - group B
  - non-hemolytic
    - Enterococcus

    - S. aureus
    - S. epidermidis
    - S. saprophyticus

Mycoplasma
- M. hominis
- M. genitalium

Ureaplasma
- U. urealyticum

*Anaerobic bacteria not considered.
17. ABBREVIATIONS USED IN THE TEXT

This list is not comprehensive for the most common abbreviations.

- **ABU**: asymptomatic bacteriuria
- **ACE**: angiotensin-converting enzyme
- **ADPKD**: adult dominant polycystic disease
- **APCKD**: adult polycystic kidney disease
- **BLI**: β-lactamase inhibitor
- **BPH**: benign prostatic hyperplasia
- **CPPS**: chronic pelvic pain syndrome
- **CPSI**: Chronic Prostatitis Symptom Index
- **CT**: computed tomography
- **CAUTIs**: catheter-associated urinary tract infections
- **DMSA**: dimercaptosuccinic acid
- **DTPA**: diethylenetriamine pentaacetate
- **EPS**: expressed prostatic secretion
- **EUCAST**: European Committee for Antimicrobial Susceptibility Testing
- **G6PD**: glucose-6-phosphate dehydrogenase
- **GFR**: glomerular filtration rate
- **IDSA**: Infectious Diseases Society of America
- **IL**: interleukin
- **IPCN**: International Prostatitis Collaborative Network
- **IVU**: intravenous urography
- **LUTS**: lower urinary tract symptom
- **MAG-3**: mercaptoacetyllyglycine
- **MRI**: magnetic resonance imaging
- **MRSA**: methicillin-resistant Staphylococcus aureus
- **MSU**: mid-stream sample of urine
- **NCCLS**: National Committee for Clinical Laboratory Standards
- **NIDDK**: National Institute of Diabetes and Digestive and Kidney Diseases
- **NIH**: National Institutes of Health
- **PCP**: Pneumocystis carinii pneumonia
- **PSA**: prostate-specific antigen
- **SIRS**: systemic inflammatory response syndrome
- **SMX**: sulphamethoxazole
- **SSI**: surgical site infection
- **STD**: sexually transmitted disease
- **SWL**: shockwave lithotripsy
- **TMP**: trimethoprim
- **TNF**: tumour necrosis factor
- **TRUS**: transrectual ultrasound
- **TURP**: transurethral resection of the prostate
- **US**: ultrasonography
- **UTI**: urinary tract infection
- **VB1**: first-voided urine
- **VB2**: mid-stream urine
- **VB3**: voided bladder urine-3
- **VCU**: voiding cystourethography
- **VUR**: vesicoureteric reflux
- **WBC**: white blood cells

**Conflict of interest**

All members of the Urological Infections Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.
**TABLE OF CONTENTS**

6. ABBREVIATIONS USED IN THE TEXT 114
1. INTRODUCTION

Urinary incontinence (UI) is an extremely common complaint in every part of the world. It causes a great deal of distress and embarrassment, as well as significant costs, to both individuals and societies. Estimates of prevalence vary according to the definition of incontinence and the population studied. However, there is universal agreement about the importance of the problem in terms of human suffering and economic cost.

These Guidelines from the European Association of Urology (EAU) Working Panel on Urinary Incontinence are written by urologists for urologists, and aim to provide sensible and practical evidence-based guidance on the clinical problem of UI rather than an exhaustive narrative review. Such a review is already available from the International Consultation on Incontinence (1), and so the EAU Guidelines do not describe the causation, basic science, epidemiology and psychology of UI. The focus of these Guidelines is entirely on assessment and treatment reflecting clinical practice. The Guidelines also do not consider patients with UI caused by neurological disease, as this is covered by complementary EAU Guidelines (2).

The EAU Panel knew that they would find little evidence for some issues and a lot of evidence for others. This difference, to some extent, reflects the greater funding available for industry-sponsored trials of drugs, the results of which are required for licensing in Europe and the USA. The less stringent regulatory requirements for the introduction of new devices or surgical techniques means that there are far fewer high-quality studies regarding these interventions. Although the lack of high-quality evidence means that judgements about the worth of interventions are prone to bias, the panel took the view that clinicians still require some guidance concerning clinical practice. In these circumstances, we have summarised the available evidence and made recommendations, with uncertainty reflected by a lower grade of recommendation.

1.1 Methodology

The Panel decided to rewrite the existing EAU Guidelines on UI using a new methodological approach and to present them in a format that most closely reflected the approach to management of UI. The current Guidelines provide:

- A clear clinical pathway (algorithm) for common clinical problems. This can provide the basis for thinking through a patient’s management and also for planning and designing clinical services.
- A brief but authoritative summary of the current state of evidence on clinical topics, complete with references to the original sources.
- Clear guidance on what to do or not to do, in most clinical circumstances. This should be particularly helpful in those areas of practice for which there is little or no high-quality evidence.

1.1.1 PICO questions

The ‘PICO’ (Population, Intervention, Comparison, Outcome) framework was used to develop a series of clinical questions that would provide the basis of presentation of the guidelines (3,4). There are four elements to each clinical question:

- population;
- intervention;
- comparison;
- outcome.

The wording of each PICO is important because it directs the subsequent literature research. For each element, the EAU Panel listed every possible wording variation.

In these Guidelines, the four traditional domains of urological practice are presented as separate chapters, namely assessment and diagnosis, conservative management, drug therapy and surgical treatments.

In this second edition of these new EAU Guidelines for Urinary Incontinence, the Panel has focused largely on the management of a ‘standard’ patient. The Panel has referred in places to patients with ‘complicated incontinence’, by which we mean patients with associated morbidity, a history of previous pelvic surgery, surgery for UI, radiotherapy and women with associated genitourinary prolapse. This second edition does not review the prevention of UI, or the management of fistula, but these issues will be fully addressed in future editions.

1.1.2 Search strategies

A number of significant narrative reviews, systematic reviews and guidance documents have been produced within the last few years. The Panel agreed that the literature searches carried out by these reviews would be accepted as valid. Thus, for each PICO question, a search was carried out with a start date that was...
the same as the cut-off date for the search associated with the most recent systematic review for the PICO topic. This pragmatic selection approach, while being a compromise and open to criticism, made the task of searching the literature for such a large subject area possible within the available resources. For each section, the latest cut-off date for the relevant search is indicated.

Thus, for each PICO, a subsequent literature search was carried out (confined to Medline and Embase and to English language articles), which produced an initial list of abstracts. The abstracts were each assessed by two Panel members, who selected the studies relevant to the PICO question, and the full text for these was retrieved (Table 1).

<table>
<thead>
<tr>
<th>Chapter</th>
<th>Latest ‘cut-off’ date for search</th>
</tr>
</thead>
<tbody>
<tr>
<td>Assessment and diagnosis</td>
<td>28 June 2012</td>

<td>Conservative therapy</td>
<td>28 June 2012</td>
</tr>
<tr>
<td>Drug therapy</td>
<td>28 June 2012</td>
</tr>
<tr>
<td>Surgical therapy</td>
<td>9 July 2012</td>
</tr>
</tbody>
</table>

Each PICO was then assigned to a Panel member, who read the papers and extracted the evidence for incorporation into standardised evidence tables, which are maintained online as an evidence resource for the Panel. This resource will continue to be available and will be continuously updated with each repeated literature review.

The existing evidence from previous systematic reviews and new evidence were then discussed for each PICO in turn at a Panel meeting generating consensus conclusions. To help standardise the approach, modified process forms (data extraction and considered judgment) from the Scottish Intercollegiate Guidelines Network (SIGN) were used.

The quality of evidence for each PICO is commented on in the text, aiming to synthesise the important clinical messages from the available literature and is presented as a series of levels of evidence summaries in the EAU format (Table 2).

From the evidence summaries, the Panel then produced a series of action-based recommendations, again graded according to EAU standards (Table 3). These grades aim to make it clear what the clinician should or should not do in clinical practice, not merely to comment on what they might do.

The Panel has tried to avoid extensive narrative text. Instead, algorithms are presented for both initial and specialised management of men and women with non-neurogenic UI. Each decision node of these algorithms is clearly linked back to the relevant evidence and recommendations.

It must be emphasised that clinical guidelines present the best evidence available to the expert Panel at the time of writing. There remains a need for ongoing re-evaluation of the current guidelines by the Panel. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients; they aim to focus decisions. Clinical decisions must also take into account the patient’s personal values, preferences and specific circumstances.

1.1.3 Level of evidence and grade of recommendation

References used in the text have been assessed according to their level of scientific evidence (Table 2), which is a modification of the system used by the Oxford Centre for Evidence Based Medicine (CEBM). A similar modification has been used for the Guidelines’ recommendations. The aim of grading recommendations is to provide transparency between the underlying evidence and the recommendation given. Diagnostic studies were assessed according to a similar modification of the CEBM evidence levels for diagnostic accuracy and prognosis.
Table 2: Level of evidence (LE)*

<table>
<thead>
<tr>
<th>LE</th>

<td>Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.</td>
</tr>
<tr>
<td>4</td>
<td>Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.</td>
</tr>
</tbody>
</table>

*Modified from Sackett et al. (5)

It should be noted that when recommendations are graded, there is not an automatic relationship between the level of evidence and grade of recommendation. The availability of randomised controlled trials (RCTs) may not necessarily translate into a Grade A recommendation if there are methodological limitations or a disparity in published results.

Alternatively, an absence of high-level evidence does not necessarily preclude a Grade A recommendation; if there is overwhelming clinical experience and consensus to support a high-level recommendation, then a Grade A recommendation can be given. In addition, there may be exceptional situations in which corroborating studies cannot be performed, perhaps for ethical or other reasons. In this case, unequivocal recommendations are considered helpful for the clinician. Whenever this occurs, it has been clearly indicated in the text with an asterisk, as ‘upgraded based on Panel consensus’. The quality of the underlying scientific evidence is a very important factor, but it has to be balanced against benefits and burdens, personal values and preferences when a grade is assigned (6-8).

The EAU Guidelines Office does not perform cost assessments nor can they address local/national preferences in a systematic fashion.

Table 3: Grade of recommendation (GR)*

<table>
<thead>
<tr>
<th>GR</th>

</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial.</td>
</tr>
<tr>
<td>B</td>
<td>Based on well-conducted clinical studies, but without randomised clinical trials.</td>
</tr>
<tr>
<td>C</td>
<td>Made despite the absence of directly applicable clinical studies of good quality.</td>
</tr>
</tbody>
</table>

*Modified from Sackett et al. (5).

1.2 Publication history

The complete update in 2009 was largely a synthesis of guidance by the International Consultation on Urological Diseases (ICUD) and the National Institute for Health and Clinical Evidence (NICE), as was the 2010 edition. In 2011, an addendum was added on the use of drugs, now incorporated in the full text under Chapter 4. The 2012 edition was also partly based on guidance from the ICUD and NICE, but new searches were conducted from June 2008 to 2011; these have now been updated with new searches up to September 2012.

Two separate addenda are provided on mixed urinary incontinence (MUI) and management of UI in the elderly (see Appendices A and B). We expect to update these Guidelines annually.

A quick reference guide, presenting the main findings of the Urinary Incontinence Guidelines, is also available, as well as two scientific publications in the journal of the EAU, European Urology (9,10). All texts can be viewed and downloaded for personal use at the society website: http://www.uroweb.org/guidelines/online-guidelines/.

This document was peer-reviewed prior to publication.

http://www.icud.info/incontinence.html
1.4 Use in different healthcare settings and by healthcare professionals

The Guidelines have been written for urologists and for use in any healthcare setting in Europe. However, the Panel recognises that many different health professionals besides urologists use EAU Guidelines. The Panel also recognises that a patient’s first point of contact may not always be a urologist, and that the healthcare professional delivering treatment, e.g. physiotherapy, may also not be a urologist. For this reason, some healthcare professionals may find that the Guidelines do not explain a particular topic in enough detail for their needs, e.g. delivery modalities for pelvic floor muscle training (PFMT).

1.5 Terminology

Evidence summaries provide a succinct summary of what the currently available evidence tells us about an individual clinical question. They are presented according to the levels of evidence used by the EAU.

Recommendations have been deliberately written as ‘action-based’ sentences. The following words or phrases are used consistently throughout the Guidelines, as follows:

- **Consider** an action. This word is used when there is not enough evidence to say whether the action causes benefit or risk to the patient. However, in the opinion of the Panel, the action may be justified in some circumstances. Action is optional.

- **Offer** an action. This word is used when there is good evidence to suggest that the action is effective, or that, in the opinion of the Panel, it is the best action. Action is advisable.

- **Carry out (perform)** an action. **Do** something. This phrase is used when there is strong evidence that this is the only best action in a certain clinical situation. Action is mandatory.

- **Do not** perform (i.e. avoid) an action. This phrase is used when there is high-level evidence that the action is either ineffective or is harmful to the patient. Action is contraindicated.
2. ASSESSMENT AND DIAGNOSIS

2.1 History and physical examination
Taking a careful clinical history is fundamental to the clinical process. Despite the lack of formal evidence, there is universal agreement that taking a history should be the first step in the assessment of anyone with UI. The history should include details of the type, timing and severity of UI, associated voiding and other urinary symptoms. The history should allow the UI to be categorised into stress urinary incontinence (SUI), urge urinary incontinence (UUI) or mixed urinary incontinence (MUI). It should also identify patients who need rapid referral to a specialist. These include patients with associated pain, haematuria, a history of recurrent urinary tract infections (UTIs), pelvic surgery (particularly prostate surgery) or radiotherapy, constant leakage suggesting a fistula, voiding difficulty or suspected neurological disease. In women, an obstetric and gynaecological history may help to understand the underlying cause and identify factors that may impact on treatment decisions. The patient should also be asked about other ill health and for the details of current medications, as these may impact on symptoms of UI, or cause it.

Similarly, there is little evidence that carrying out a clinical examination improves care, but wide consensus suggests that it remains an essential part of assessment of people with UI. It should include abdominal examination, to detect an enlarged bladder or other abdominal mass, and perineal and digital examination of the rectum (prostate) and/or vagina. Examination of the perineum in women includes an assessment of oestrogen status and a careful assessment of any associated pelvic organ prolapse (POP). A cough test may reveal SUI if the bladder is sufficiently full and pelvic floor contraction can be assessed digitally.

2.2 Patient questionnaires
Questionnaires may be symptom scores, symptom questionnaires, condition-specific patient-reported outcome measures (PROMS) or generic health-related quality of life (HRQoL) measures. Questionnaires are widely used to record patients’ symptoms in a standardised way, including their severity and impact, and have been used to monitor the condition over time, e.g. in the context of changes related to treatment. During the last 10 years, many questionnaires have been developed and researched, including ones specifically designed for lower urinary tract symptoms (LUTS), POP, faecal incontinence and both condition-specific and generic quality of life (QoL).

Questionnaires should have been validated for the language in which they are being used, and all measures that are used for outcome evaluation must have been shown to be sensitive to change. Many questionnaires have been developed by commercial organisations; there is a risk that the way such questionnaires are developed could produce questionnaires sensitive to small changes of little clinical importance. The methodology for their development was reviewed in the 4th International Consultation on Incontinence in 2008 (1).

2.2.1 Questions
• In adults with UI, does assessment using either urinary symptom or QoL questionnaires improve the treatment outcome for UI?
• In adults with UI, does assessment of the patient perspective (concerns or expectations) improve patient outcomes, regarding either urinary symptoms or QoL, compared to no patient-reported assessment?

2.2.2 Evidence
Although many studies have investigated the validity and reliability of questionnaires and PROMs, most have taken place in adults without UI. This greatly limits the extent to which results and conclusions from these studies can be applied in adults with UI. There is low-level evidence that questionnaires may be more sensitive to change than a bladder diary. A randomised crossover study (2) suggested that web-based questionnaires may be more acceptable to patients than paper versions (3).

2.2.3 Research priorities
There is a lack of knowledge about whether using questionnaires to assess urinary symptoms or QoL helps to improve outcomes in adults with UI. Further research is needed to compare the use of questionnaires to assess urinary symptoms and/or QoL in addition to standard clinical assessment versus clinical measures alone. Patients should be closely involved in the design of such studies.

2.2.4 References

2.3 Voiding diaries
Measurement of the frequency and severity of LUTS is an important step in the evaluation and management of lower urinary tract dysfunction, including UI. Voiding diaries are a semi-objective method of quantifying symptoms, such as frequency of urinary incontinence episodes. They also quantify urodynamic variables, such as voided volume and 24-hour or nocturnal total urine volume. Voiding diaries are also known as micturition time charts, frequency/volume charts and bladder diaries.

Discrepancy between diary recordings and the patient rating of symptoms, e.g. frequency or UI, can be useful in patient counselling. In addition, voided volume measurement can be used to support diagnoses, such as overactive bladder (OAB) or polyuria. Diaries can also be used to monitor treatment response and are widely used in clinical trials as a semi-objective measure of treatment outcome.

In patients with severe UI, a bladder diary is unlikely to accurately report total urine output and the discrepancy between functional bladder capacity and total bladder capacity may be large.

2.3.1 Questions
• In adults with UI, what are the reliability, diagnostic accuracy and predictive value of a voiding diary compared to patient history or symptom score?
• How does the accuracy of a computerised voiding diary compare to a paper diary?

2.3.2 Evidence
Two recent articles have suggested a consensus has been reached in the terminology used in voiding diaries (1,2):
• Micturition time charts record only the times of micturitions for a minimum of 24 continuous hours.
• Frequency volume charts record voided volumes and times of micturitions for a minimum of 24 hours.
• Bladder diaries include information on incontinence episodes, pad usage, fluid intake, degree of urgency and degree of UI.

Several studies have compared patients’ preference for, and the accuracy of, electronic and paper voiding diaries in voiding dysfunction (3-7). Several studies have compared shorter (3 or 5 days) and longer diary durations (7 days) (8-14). The choice of diary duration appears to be based upon the possible behavioural therapeutic effect of keeping a diary rather than on validity or reliability.

Two studies have investigated the reproducibility of voiding diaries in both men and women (9,14). Further studies investigated the variability of diary data within a 24-hour period (15) and compared voided volumes recorded in diaries with those recorded on uroflowmetry (16). Other studies have investigated the correlation between data obtained from voided diaries and standard symptom evaluation (17-20).
One study investigated the effect of diary duration on the observed outcome of treatment of LUTS (21). Another study found that keeping a voiding diary had a therapeutic benefit (22).

In conclusion, voiding diaries give reliable data on lower urinary tract function. There remains a lack of consensus about how long a diary should be kept and how well diary data correlate with some symptoms.

### References

Reagent strip ('dipstick') urinalysis may detect infection, proteinuria, haematuria and glycosuria:
- Nitrite and leukocyte esterase may indicate a UTI.
- Protein may indicate infection and/or renal disease.
- Blood may indicate malignancy (or infection).
- Glucose may indicate diabetes mellitus.

It is generally agreed that dipstick urinalysis provides sufficient screening information in both men and women with UI. Microscopy and other tests may be necessary to confirm any abnormalities identified on dipstick analysis. Urinalysis is usually carried out on a mid-stream urine specimen, but an analysis of initial voided and terminal urine samples may be required for the assessment of urethral and prostate infections.

### 2.4.1 Questions
- In adults with UI, what is the diagnostic accuracy of urinalysis for UTIs?
- What is the benefit for UI of treating UTIs?

### 2.4.2 Evidence
In both men and women with UI, the diagnosis of a UTI by positive leucocytes or nitrates using urine culture as the reference standard had a low sensitivity and very high specificity (3,4). A negative urine dipstick test in patients with UI therefore excludes a UTI with a high degree of certainty.

There is a consensus that urinalysis should be a standard part of the basic evaluation of UI, irrespective of sex, age or aetiology.

2.4.3 References

2.5 Post-voiding residual volume

Post-voiding residual (PVR) volume (also known as residual urine, bladder residual) is the amount of urine that remains in the bladder after voiding. It indicates poor voiding efficiency, which may result from a number of contributing factors. It is important because it may worsen symptoms and, more rarely, may be associated with upper urinary tract dilatation and renal insufficiency. Both bladder outlet obstruction and detrusor underactivity contribute to the development of PVR. The presence of PVR may be associated with UI symptoms.

Post-voiding residual can be measured by catheterisation or ultrasound (US). The prevalence of PVR is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume.

2.5.1 Question

In adults with UI, what are the diagnostic accuracy and predictive value of measurements of PVR?

2.5.2 Evidence

Most studies investigating PVR have not included patients with UI. Although some studies have included women with UI and men and women with LUTS, they have also included children and adults with neurogenic UI. In general, the data on PVR can be applied with caution to adults with non-neurogenic UI. The results of studies investigating the best method of measuring PVR (1-6) have led to the consensus that ultrasound (US) measurement of PVR is better than measurement using catheterisation.

Several studies have evaluated PVR in different subjects and patient cohorts (7-17). In peri- and post-menopausal women without significant LUTS or pelvic organ symptoms, 95% of women had a PVR < 100 mL (9). A comparison of women with and without LUTS suggested that symptomatic women had a higher incidence of elevated PVR (11). In women with UUI, a PVR > 100 mL was found in 10% of cases (18). Other research has found that a high PVR is associated with POP, voiding symptoms and an absence of SUI (8,12,14,15).

In women with SUI, the mean PVR was 39 mL measured by catheterisation and 63 mL measured by US, with 16% of women having a PVR > 100 mL (16). Overall, women with symptoms of lower urinary tract or pelvic floor dysfunction and POP have a higher rate of elevated PVR compared to asymptomatic subjects.
There is evidence to suggest that elevated PVR should be particularly looked for in patients with voiding symptoms (18-21). There is no evidence to define a threshold between normal and abnormal PVR values. Expert opinion has therefore been used to produce definitions of elevated PVR values (22-25), but unfortunately these differ from one another. There is a lack of evidence to support the routine measurement of PVR in patients with UI (26-30).

2.5.3 **Research priority**

Further research is required to evaluate whether combining non-invasive tests provides greater diagnostic accuracy and prognostic value than tests viewed in isolation.

2.5.4 **References**

2.6 Urodynamics

In clinical practice, ‘urodynamics’ is generally used as a collective term for all tests of bladder and urethral function. These Guidelines will review both non-invasive estimation of urine flow, i.e. uroflowmetry, and invasive tests, including multichannel cystometry, ambulatory monitoring and video-urodynamics, and different tests of urethral function, such as urethral pressure profilometry, Valsalva leak point pressure estimation and retrograde urethral resistance measurement.

Multichannel cystometry, ambulatory monitoring and video-urodynamics aim to observe the effects on intravesical and intra-abdominal pressures while reproducing a patient’s symptoms. Bladder filling may be artificial or physiological and voiding is prompted. Any incontinence observed may be categorised as SUI, detrusor overactivity (DO) incontinence, a mixture of SUI/DO incontinence, or, rarely, urethral relaxation incontinence. A test may fail to reproduce a patient’s symptoms because of poor diagnostic accuracy or because the symptoms are not directly attributable to an urodynamically measurable phenomenon.

Urodynamic testing is widely used as an adjunct to clinical diagnosis, to direct decisions about treatment and to provide prognostic information. When clinical diagnosis is difficult because of an unclear history or inconclusive examination, urodynamics may provide the only ‘diagnosis’ available. Although it is unlikely that carrying out a test, in itself, would alter the outcome of treatment, it remains possible that the test results would influence treatment decisions to such an extent that better outcomes were achieved. This has been the rationale for using urodynamics prior to surgery.

2.6.1 Question

In adults with UI, what is the diagnostic accuracy and predictive value of uroflowmetry, i.e. the measurement of maximum urinary flow rate ($Q_{\text{max}}$) and urodynamic testing?

2.6.2 Evidence

2.6.2.1 Repeatability

Although a recent study has suggested that test retest variability is acceptable (1), many older studies have shown a variability of up to 15% in different urodynamic parameters (2-9). No published studies on the reliability of ambulatory monitoring were found.

Various techniques are used to measure urethral profilometry. Individual techniques are generally reliable in terms of repeatability, but results may vary between different techniques, so that one type of test cannot be compared meaningfully to another (10-12).

The measurement of abdominal or Valsalva leak point pressures has not been standardised. It has not been possible to correlate consistently any method of measuring Valsalva leak point pressure with either UI severity or other measures of urethral function (13-18).

Studies of technical accuracy have included adults with LUTS, with or without UI. The studies used different equipment and lacked standardised techniques (19,20). As with all physiological investigation, results have shown a wide range of variability.

Inter-rater and intra-rater reliability of video-urodynamics for the severity and type of SUI is good (21).

2.6.2.2 Diagnostic accuracy

The diagnostic accuracy of urodynamics cannot be measured against a ‘gold standard’ since all incontinence diagnoses are defined in urodynamic terms. Ambulatory urodynamics may detect unexpected physiological variance from normal, more often than conventional cystometry, but the clinical relevance of this is uncertain (22,23).
Detrusor overactivity may be found in asymptomatic patients, while normal cystometry is found in patients who are clearly symptomatic. There have been many studies of variable quality, investigating the relationship between UI symptoms and subsequent urodynamic findings. For their UK-based guidance, NICE reviewed 11 studies (24), which investigated the relationship between clinical diagnosis and urodynamic findings and the diagnostic accuracy of urodynamic measurement, specifically in females. The Panel found that no new evidence has been published since 2005 up until September 2012.

There is a consensus that urodynamic tests should aim to reproduce the patient’s symptoms and should be performed with attention to technical and methodological detail. In clinical practice, urodynamic testing (cystometry) may help to provide, or confirm, a diagnosis, predict treatment outcome, or facilitate discussion during a consultation. It is unlikely that any test, in itself, would alter the outcome of treatment. However, it is possible that the way test results influence treatment choices may have an impact on this. For all these reasons, urodynamics is often performed prior to invasive treatment for UI.

2.6.2.3 Does urodynamics influence the outcome of conservative therapy?
A meta-analysis of 129 studies of diagnostic tests for incontinence, using economic modelling, concluded that urodynamics was not cost-effective in a primary care setting (25).

A recent Cochrane review included seven RCTs that examined the question of whether urodynamics influences the outcome of all therapy for UI. The review showed that urodynamic tests influenced clinical decision-making (increased likelihood of using drugs in two trials or to avoid surgery in three trials). However, there was not enough evidence to suggest that this altered the clinical outcome of treatment (26). Subanalysis of a RCT comparing fesoterodine to placebo, and another dose finding study of botulinum toxin (27) showed no predictive value, in terms of drug response, for the urodynamic diagnosis of DO (28).

2.6.2.4 Does urodynamics influence the outcome of surgery for SUI?
Post-hoc analysis of surgical RCTs has shown the risk of failure of SUI surgery is higher in women who have worse leakage or urodynamically demonstrable USI (29).

One high-quality RCT compared office evaluation alone to office evaluation and urodynamics in women with clinical demonstrable SUI about to undergo surgery for SUI. There was no difference in levels of UI or any secondary outcome at 12 months’ follow-up (30). Another similar RCT stopped recruitment early and was redesigned, but the outcomes of the second-phase study have not yet been published (31).

Various studies have examined the relationship between measures of poor urethral function, i.e. low maximal urethral closure pressure, low Valsalva leak point pressure, and subsequent failure of surgery. Some studies found a correlation between low urethral pressures and surgical failure, while other studies did not (32-35). A correlation, in itself, was not necessarily predictive.

2.6.2.5 Does urodynamics help to predict complications of surgery?
The presence of pre-operative DO has more consistently been associated with development of post-operative UUI. Post-hoc analysis of an RCT comparing the autologous fascial sling to Burch colposuspension showed inferior outcomes for women who suffered pre-operative urgency (44). However pre-operative urodynamics had failed to predict this outcome (45). Other case series, however, have shown there is a consistent association of poor outcomes with pre-operative DO, although the predictive value was not calculated (46,47).

2.6.2.6 Does urodynamics influence the outcome of surgery for DO?
No studies were found on the relationship between urodynamic testing and subsequent surgical outcome for DO. However, most studies reporting surgical outcomes for DO have included only patients with urodynamically proven DO or DO incontinence. Higher-pressure DO appears to be consistently associated with surgical failure and persistent or de novo urgency. As with other suggested ‘predictors’, the predictive value has not often been formally calculated (32,48,49). Pre-operative urgency was resolved in some patients (50,51).

2.6.2.7 Does urodynamics influence the outcome of treatment for post-prostatectomy UI in men?
There are no RCTs examining the clinical usefulness of urodynamics in post-prostatectomy UI. However, many case series have demonstrated the ability of urodynamics to distinguish between different causes of UI (52-54).
The ability of urodynamic testing to predict surgical outcome for post-prostatectomy UI is inconsistent (55, 56).

2.6.3 **Research priority**

Does any individual urodynamic test influence the choice of treatments or prediction of treatment outcome for UI?

2.6.4 **References**

2.7 Pad testing
A well-designed continence pad will contain any urine leaked within a period of time and this has therefore been used as a way of quantifying leakage. Although the International Continence Society has attempted to standardise pad testing, there remains variation in the duration of the test and the physical activity undertaken during the test.
2.7.1 **Question**
In adults with UI, what are the reliability, the diagnostic accuracy and predictive value of pad testing?

2.7.2 **Evidence**
The use of pad tests has been reviewed in the 4th International Consultation on Incontinence. Many studies have investigated the use of short-term and long-term pad tests to diagnose UI (1). Several other studies have investigated the correlation between pad test results and symptom scores for UI or LUTS (2-6). In addition, several studies have analysed the reproducibility of pad tests (2,7-11).

A few studies have tried to use pad testing to predict the outcome of treatment for UI with inconsistent results (12-14). Currently, pad tests are mostly used as objective outcomes in clinical trials. However, pad tests may be helpful in daily clinical practice, and most guidelines already include the use of pad testing to evaluate treatment outcome (15, 16). There is good evidence to show that repeat pad testing can detect change following treatment for UI (17-19).

2.7.3 **Research priority**

- Does the results of pad testing influence the choice of treatments or the prediction of the outcome of treatment for UI?
- Does the amount of physical activity influence the outcome of 24-hour pad testing leading to overestimation of the severity of incontinence?

2.7.4 **References**

2.8 Imaging

Imaging improves our understanding of the anatomical and functional abnormalities that may cause UI. In clinical research, imaging is used to understand the relationship between conditions of the central nervous system (CNS) and of the lower urinary tract in causing UI, and to investigate the relationship between conditions of the lower urinary tract and treatment outcome.

Ultrasound and magnetic resonance imaging (MRI) have replaced X-ray imaging, as both procedures are safer and can provide both qualitative and quantitative data on the kidneys, bladder neck and pelvic floor. Ultrasound is preferred to MRI because of its ability to produce three-dimensional and four-dimensional (dynamic) images at lower cost and wider availability. The current lack of knowledge about the pathophysiology of UI makes it difficult to carry out research in the imaging of UI. Studies on lower urinary tract imaging in patients with UI often include an evaluation of surgical outcomes, making design and conduct of these trials particularly challenging.
2.8.1 Questions

- In adults with UI, what is the reliability and accuracy of imaging in the diagnosis of UI?
- In adults do the results of imaging influence the choice, help predict outcome or help evaluate outcome of treatments for UI?

2.8.2 Evidence

Several imaging studies have investigated the relationship between sphincter volume and function in women (1) and between sphincter volume and surgery outcome in men and women (2,3). Imaging of urethral anastomosis following radical prostatectomy has been used to investigate continence status (4). However, no imaging test has been shown to predict the outcome of treatment for UI.

Many studies have evaluated the imaging of bladder neck mobility by US and MRI, and concluded that UI cannot be identified by a particular pattern of urethrovesical movements (5). In addition, the generalised increase in urethral mobility after childbirth does not appear to be associated with de novo SUI (6).

There is a general consensus that MRI provides good global pelvic floor assessment, including POP, defecatory function and integrity of the pelvic floor support structure (7). However, there is a large variation in MRI interpretation between institutions (8) and little evidence to support its clinical usefulness.

Studies have assessed the use of imaging to effect of mid-urethral sling insertion for SUI. One study suggested that mid-urethral sling placement decreased mobility of the mid-urethra but not mobility of the bladder neck (9). In addition, the position of mid-urethral slings with respect to the pubis has been associated with the cure of UI (10).

No studies were found which specifically addressed the PICO question for this section. Lower urinary tract imaging does not appear to provide any clinical benefit in patients with UI (11). Despite this, however, some experts continue to recommend imaging (12-15).

3. CONSERVATIVE TREATMENT

In clinical practice, it is a convention that non-surgical therapies are tried first because they usually carry the least risk of harm.
